Preface to the Fourth Edition

The extensive revisions made in this the fourth edition of *Bacterial and Mycotic Infections of Man* go far beyond bringing up to date the factual contents of earlier editions While the general structure and the purpose of the book remain unchanged much new material has been added to strengthen the theoretical basis of medical microbiology and to enlarge the understanding of its application to disease processes

The first chapters deal with the historical evolutionary and ecologic aspects of microbiologic sciences They are followed by a study in some depth of modern microbial morphology genetics and metabolism then of the constituents and the properties of microorganisms more directly relevant to their pathogenicity

The second part of the book deals with host response to infection Host resistance mechanisms are first considered with regard to the body as a whole then with special emphasis on phagocytic cells and humoral agencies Hypersensitivity phenomena and physiologic and pathologic responses to microbial invasion complete the discussion of the general disorders encountered in infectious processes

Chapters 14 through 37 deal with specific groups of microorganisms Each of these chapters has been rewritten and brought up to date One new chapter has been added to cover atypical pneumonia caused by Mycoplasma an entity which had not been defined at the time the previous edition was published

The book ends with three new chapters devoted to the general and practical problems of epidemiology prevention and therapy

In the previous edition an effort had been made to restrict the number of references in order to save space The experience of those who have used the book makes it clear that this was false economy therefore we have greatly enlarged the list of pertinent references at the end of each chapter

The first three editions of *Bacterial and Mycotic Infections of Man* had been published under the sponsorship of the National Foundation While the present fourth edition is being published independently of it we wish to thank the Foundation for its early encouragement to prepare a book focused on the needs of the student the physician and the investigator interested in the problems of microbial diseases

Preface to the First Edition

This volume was designed to convey to the medical student—and we hope also to the practitioner of medicine—some knowledge of the bacteria actinomycetes and molds pathogenic for man as well as of the phenomena which characterize the infectious process Infections caused by viruses and rickettsiae are treated in a companion volume edited by Dr T M Rivers

Medical microbiology is the study of host parasite relationships and not that of microorganisms alone considered as independent living agents It is concerned with those aspects of the structure and the properties of parasites which play a part in their pathogenic behavior and with the multiple manifestations of the response of the invaded host to their constituents and products The general chapters of this treatise are therefore devoted to the facts and the problems concerning parasite and host which have a bearing—often immediate but at times only potential and remote—on infectious disease

A few words may be necessary to justify the order in which the different pathogenic agents are described in subsequent chapters This order was adopted to illustrate by the extensive treatment of a few selected examples the multiple facets of the problem of infection Thus the diphtheria bacillus is discussed first to introduce the concept of toxemia and of antitoxic immunity As a counterpart pneumococcus infections are then selected to emphasize the problems of antibacterial immunity Streptococci on the other hand lend themselves to the demonstration that a given microbial agent can exhibit multiple pathogenic potentialities and that tissues can respond in many different ways to its presence Tuberculosis illustrates particularly well the acute (exudative) and chronic (proliferative) pathologic processes accompanying infection and the altered reactivity of the body (allergy) which results from previous exposure to the bacillus All these aspects of the infectious process appear in more or less modified form in the other microbial diseases and give to each of them its peculiar character

This treatise is the result of the co operative effort of many experts and naturally reflects their individual outlooks I wish to thank them all in particular for their willingness to aim at some measure of uniformity in our common undertaking The National Foundation for Infantile Paralysis has given generous financial support to the preparation of the book and shares with us the hope that it may contribute something to the understanding of the general problems of infection

The Evolution of Medical Microbiology

THE DISCOVERY OF MICROBIAL LIFE

Bacteriology is one of the very few biologic sciences *if not the only one which can* trace its origin to a single person one well documented observation and an instrument still *in existence On September 17 1683* Antonj van Leeuwenhoek (1632 1723) sent from Delft (Holland) where he lived to the Royal Society in London of which he was a correspondent the description of a new kind of animalcule smaller than any thing yet known he reported similar observations in another letter dated September 1692 Both letters were illustrated with drawings which leave no doubt that Leeuwenhoek had really seen bacteria in fact he clearly differentiated the main morphologic types which are still recognized today and he gave an excellent account of bacterial motility

Contrary to what is often stated Leeuwenhoek did not invent the *microscope Even* though the compound microscope was al*ready known in his time he never owned one* and made all his observations with a multiplicity of single lens microscopes of his own design and making He was an expert lens grinder and made numerous small lenses each mounted in a different way to suit particular purposes His simple instruments could give magnifications ranging from 40 to 275 diameters and he probably used some kind of darkfield illumination However these statements are conjectural because he was very secretive about his methods of observation he reported his findings in great details but *never describ d his technics* Fortunately he willed some of his instruments to the Royal Society which has preserved them ever since (Dobell 1932)

Another unique feature of the history of bacteriology is that it gives an unequivocal answer to a question much debated by his*torians of science The question is* whether science originates from sheer curiosity and *the desire to know more about the world* or from man s urge to achieve practical ends and *master his environment* The answer to this question is very clear in the case of Leeuwenhoek He earned his living as a draper and as an employee of the city of Delft Lens grinding and the exploration of the microscopic world were activities from *which he could not* possibly derive any material reward beyond the satisfaction of curiosity He worked alone had no sponsor and had no practical application in mind when he chanced to discover bacteria in an infusion of pepper and in material scraped from his teeth Entertainingly enough it was only a very few years ago—i e almost 300 years after his initial observations—that the presence of bacteria on teeth was first shown to be of practical importance as a cause of dental caries

In fact the science of bacteriology remained a completely disinterested form of knowledge for almost 200 years after Leeuwenhoek s discoveries During this period much was learned of the shape the structure

The Evolution of Medical Microbiology

THE DISCOVERY OF MICROBIAL LIFE

Bacteriology is one of the very few biologic sciences if not the only one which can trace its origin to a single person one well documented observation and an instrument still in existence On September 17 1683 Antonj van Leeuwenhoek (1632 1723) sent from Delft (Holland) where he lived to the Royal Society in London of which he was a correspondent the description of a new kind of animalcule smaller than anything yet known he reported similar observations in another letter dated September 1692 Both letters were illustrated with drawings which leave no doubt that Leeuwenhoek had really seen bacteria in fact he clearly differentiated the main morphologic types which are still recognized today and he gave an excellent account of bacterial motility

Contrary to what is often stated Leeuwenhoek did not invent the microscope Even though the compound microscope was already known in his time he never owned one and made all his observations with a multiplicity of single lens microscopes of his own design and making He was an expert lens grinder and made numerous small lenses each mounted in a different way to suit particular purposes His simple instruments could give magnifications ranging from 40 to 275 diameters and he probably used some kind of darkfield illumination However these statements are conjectural because he was very secretive about his methods of observation he reported his findings in great details but never described his technics Fortunately he willed some of his instruments to the Royal Society which has preserved them ever since (Dobell 1932)

Another unique feature of the history of bacteriology is that it gives an unequivocal answer to a question much debated by historians of science The question is whether science originates from sheer curiosity and the desire to know more about the world or from man s urge to achieve practical ends and master his environment The answer to this question is very clear in the case of Leeuwenhoek He earned his living as a draper and as an employee of the city of Delft Lens grinding and the exploration of the microscopic world were activities from which he could not possibly derive any material reward beyond the satisfaction of curiosity *He worked alone* had no sponsor and had no practical application in mind when he chanced to discover bacteria in an infusion of pepper and in material scraped from his teeth Entertainingly enough it was only a very few years ago—i e almost 300 years after his initial observations—that the presence of bacteria on teeth was first shown to be of practical importance as a cause of dental caries

In fact the science of bacteriology remained a completely disinterested form of knowledge for almost 200 years after Leeuwenhoek s discoveries During this period much was learned of the shape the structure

FIG 1 Antonj van Leeuwenhoek (1632 1723)

the size and the classification of bacteria as well as of their distribution and abundance in nature The development reached by such a purely descriptive kind of knowledge is illustrated for example in the textbook and the Atlas published in 1838 by Christian Ehrenberg (1795 1876) and in the short essay *Uber die Bacterien die Kleinsten Lebenden Wesen* published in 1872 by Ferdinand Cohn (1828 98) The more speculative aspects of bacteriologic science during the 18th and the 19th centuries revolved chiefly around the doctrines of heterogenesis and spontaneous generation

THE BIRTH OF EXPERIMENTAL MICROBIOLOGY

Throughout ancient civilizations and until late in the Renaissance it was taken for granted that plants and animals could be generated *de novo* under certain circumstances Although learned men eventually ceased to believe in the spontaneous generation of maggots and mice it long remained the general opinion that microbial life came into being through the spontaneous organization of organic substances in putrefying and fermenting materials Experimentation on this problem began in earnest around 1750

Some experimenters like the Irish priest John T Needham (1713 1781) claimed that they could bring about at will the creation of microscopic organisms in infusions previously sterilized by heat In contrast another priest Lazaro Spallanzani (1729 1799) maintained that living things however small never could be generated spontaneously from dead matter His contributions deserve special emphasis because they constitute some of the most important landmarks of experimental microbiology

Spallanzani recognized bacteria and grew them in sterilized media he observed that microbial life could occur in the absence of air and he discovered germs now called endospores of a greater resistance to heat than were the forms to which they gave rise Because of his rigid adherence to the experimental conditions required for testing the possibility of spontaneous generation he unfortunately did not inoculate his media on purpose and consequently failed to realize the general significance and technical possibilities of his work Otherwise he might well have become the founder of experimental microbiology

We cannot review here all the reasons and facts or rather pseudofacts which kept the doctrine of spontaneous generation alive until the second half of the 19th century nor can we mention the excellent experimental studies relevant to it which were carried out all over Europe during this period (For a discussion of these topics see Bulloch 1938 and Dubos 1950) However it may be said that the attitude of reasonable unprejudiced scientists on the subject was still uncertain in 1850 and that opinion was then evenly divided between the protagonists and the opponents of spontaneous generation Shortly after that time Louis Pasteur (1822 1895) entered the arena and his work convinced the scientific world that bacteria and molds never generate spontaneously With extraordinary thoroughness and elegance Pasteur demonstrated that no growth of any sort ever develops in sterilized media when all precautions are taken to keep out the microorganisms present in the surrounding air or on nearby objects But he showed also that the precautions to be taken were most exacting and that earlier investigators who had thought that they had observed spontaneous generation had not

been aware of the difficulties involved Among the many types of experiments that Pasteur designed to rule out spontaneous generation one is worth some emphasis because of its very simplicity and decisiveness and also because it finally settled the issue

A fermentable fluid was put into a flask the long neck of which was then heated and drawn into the form of an S tube (hence the name swan neck flask) When the liquid was boiled the vapor forced the air out through the orifice of the neck As the fluid became cool again the air slowly returned to the flask but was washed in the moisture that condensed in the curves of the neck after heating was interrupted Under these conditions any dust or particle carried by the air was trapped in the neck and the fluid in the flask remained clear sterile However when the neck of the flask was broken and the unwashed air was thus allowed to come into contact with the fluid microscopic life immediately began to develop Experimental difficulties arose from the fact that certain species of bacteria produce heat resistant spores In some of the early experiments these spores persisted in the fluid of the swan neck flasks that was presumed to have been sterilized by heating when they germinated they gave rise to bacterial growth even though access to outside air had been prevented Eventually these difficulties were overcome and Pasteur was able to prepare his flasks in such a manner that the broth remained sterile in them all Some of these flasks prepared almost 100 years ago are still in existence the fluid is as limpid as the day it was sterilized

For years the studies on spontaneous generation were carried out in an atmosphere of intense excitement and of passionate controversy because it was erroneously thought that the problem involved religious issues—a view which Pasteur denied strenuously In a famous lecture that he delivered at the Sorbonne in 1864 he expressed with eloquence his absolute conviction that the failure of bacteria to generate spontaneously was a purely scientific problem Presenting to his audience the swan neck flasks in which heated infusions had remained sterile in contact with natural air he exclaimed triumphantly

> I have taken my drop of water from the immensity of creation and I have taken it full of the elements appropriate to the development of microscopic organisms And I wait I watch I question it'—begging it to recommence for me the beautiful spectacle of the first creation But it is dumb dumb since these experiments were begun several years ago it is dumb because I have kept it sheltered from the only thing man does not know how to produce from the germs which float in the air from Life for Life is a germ and a germ is Life Never will the doctrine of spontaneous generation recover from the mortal blow of this simple experiment'

It is necessary to acknowledge here that present-day discussions on the origin of life seem to reopen once more the possibility of spontaneous generation As is well known the discovery that many viruses can be readily crystallized has fostered the hope that living processes can soon be identified with well defined chemical structures and processes originating from inanimate matter Many efforts are being made to imagine types of chemical reactions that would be self reproducing and thus exhibit one of the most distinctive properties of life Only time will tell to what extent today s discussions on the genesis of self-duplicating molecules of nucleic acids and of proteins really bear on the origin of life—a problem which demands philosophic definition at least as much as scientific description What is certain in any case is that modern scientific developments do not conflict with the view that all the microorganisms with which we have experience today—including the viruses—originate from structures fundamentally similar to themselves In fact it can be said that no constructive thinking on the origin of life was possible until the ancient doctrine of spontaneous generation had been discarded

One of the important by products of the studies on spontaneous generation beginning with Spallanzani s work was to provide the technical basis for experimental microbiology Exacting procedures had to be devised to destroy the microbes present in the systems under study and also to prevent the introduction of other microbes from the outside Sterilization and aseptic manipulation thus became the essential basis of microbiologic technics The necessity to grow

FIG 2 Louis Pasteur (1822 1895)

microbes in pure culture demanded investigation of their nutritional and physiologic requirements thus began theoretical microbiology which has now opened new vistas for general biology Incidental to the controversy on spontaneous generation there were discovered many important facts concerning the distribution of microbes in nature and in the various parts of the body knowledge of the natural history of microbial life made it possible to develop the technologic and medical aspects of microbiology It can be said truly that the controversies on spontaneous generation created the environment in which microbiology became aware of its problems and developed its methodology

The present essay is concerned not with the general history of microbiologic sciences but only with their medical aspects Nevertheless it seems to be important to emphasize at the outset that medical microbiology emerged in large part from studies apparently unrelated to problems of health and disease

THE GERM THEORY

The evolution of experimental microbiology has been influenced profoundly by the fact that its founder Louis Pasteur received his advanced training not in biology but in theoretical physics and chemistry (Vallery Radot 1911 Dubos 1950) In fact Pasteur s first great achievements dealt with the relation between the morphology of crystals and their ability to rotate the plane of polarized light One of the unexpected consequences of his chemical work was the discovery in 1848 that a certain mold could utilize the dextrorotatory form of tartaric acid but not its levorotatory isomer This apparently small fact determined once and for all Pasteur s subsequent scientific life by convincing him that microbes can bring about profound transformations of organic matter and that they are extraordinarily selective and specific in their activities He soon applied this general concept to the microbial transformation of sugar into lactic acid alcohol or other organic derivatives and of alcohol into acetic acid a few years later he observed that sugar was converted into butyric acid in the absence of air and thereby he discovered anaerobic life He demonstrated that each of the chemical transformations he had studied was carried out by one particular kind of microbe having very specific nutritional and environmental requirements It was in the course of these studies that he was led to rule out the accidental introduction and the *de novo* production of microbial life in fermenting fluids and thus to disprove the theory of spontaneous generation

The chemical approach to the study of microbial life immediately led Pasteur to apply his newly acquired knowledge to various fermentation industries in particular to the production of vinegar wine and beer One of the by products of his technologic activities was the technic of controlled heating for the preservation of beverages foodstuffs and other organic materials which are perishable because they are attacked readily by microbial life This technic now called

pasteurization in his honor proved of course to have large medical applications but the broader and more important relevance of Pasteur s work to medicine came from the fact that he perceived intuitively from the very beginning that the germ theory would be applicable to problems of disease In fact he expressed this conviction in his very first paper on fermentation namely the *Memoire sur la fermentation appelee lactique* which he published in 1857 when he was 35 years old (Pasteur 1857) This paper can properly be regarded as the manifesto of experimental microbiology therefore it seems justifiable to present here an outline of its contents

The 1857 *Memoire* was an attempt to demonstrate that the so-called lactic acid ferment is not just an amorphous chemical substance as was then believed but is constituted instead of organized living microscopic bodies which all resemble one another Furthermore Pasteur emphasized that the degree of acidity or alkalinity of the fermenting solutions has very profound effects on the activity of the various kinds of ferments Thus yeast produces alcohol most rapidly in an acid solution whereas the lactic acid ferment is most active at neutrality He even recognized—for the first time—the activity of certain antiseptics Onion juice he found inhibited the action of yeast but not of the lactic acid ferment

The association of a specific microbe with each fermentation the disproportion between the weight of microbe produced and the weight of matter transformed the competition between two organisms simultaneously invading the same medium resulting in the dominance of the one better adapted to the cultural conditions—all these ideas which were to grow into a large body of science and technology are forcefully set forth in the preliminary 1857 paper For this reason the *Memoire* can truly be regarded as one of the most important landmarks in the history of biochemical and biologic sciences Its fundamental spirit can be summarized in Pasteur s words

> The purity of a ferment its homogeneity its free unrestrained development from foodstuffs well adapted to its individual nature these are some of the conditions which are essential for good fermentation

Fig 3 Robert Koch (1843 1910)

With extraordinary foresight Pasteur suggested that the same principles might explain the genesis of many forms of disease and that particular kinds of microbes would be found to be responsible for particular kinds of maladies As he stated elsewhere in prophetic words

> There are similarities between the diseases of animals or man and the diseases of beer and wine If fermentations were diseases one could speak of epidemics of fermentation

THE DISTANT ORIGINS AND THE SCIENTIFIC BEGINNINGS OF MEDICAL MICROBIOLOGY

It is customary to state that medical microbiology began in 1876 when Robert Koch (1843 1910) and Pasteur demonstrated almost simultaneously and unknown to each other that the disease anthrax can be pro

duced experimentally by injecting into animals small amounts of culture of a particular microbial species (*Bacillus anthracis*) Before the significance of this laboratory achievement can be discussed adequately it is essential to emphasize that the *concept* of infection was not new in 1876 It had evolved progressively over many centuries through large numbers of careful observations shrewd hunches and bold experiments Only a few of the very many steps in this long historical development can be mentioned here

It has long been recognized of course that certain diseases are catching and that some confer protection against a second attack but although the idea of contagion passing from one individual to another was evident in diseases such as plague and syphilis it was missed completely in many other conditions Girolamo Fracastoro (1478 1553) was probably the first to state explicitly in his book *De Contagione* (1546) that infection itself is composed of minute and insensible particles and proceeds from them He wondered whether all contagion might not be a putrefaction and recognized that the infection is the same for him who has received and who has given the infection

Of course much caution is required in interpreting the early speculative writings on infectious disease because the words used by ancient authors can but rarely be applied in their modern meaning However a few concepts emerge clearly from the past Thus A Kircher (1602 80) probably the first to make direct microscopic studies of diseased tissue examined putrefying materials and even blood from plague patients On the basis of his observations he postulated that animated corpuscles scatter the seeds of contagion and that it is difficult to wash them away Therefore he recommended burning household goods and clothing suspected of carrying contagion The specificity of contagious diseases was expressed forcefully by Thomas Fuller (1654 1734) who said that one type of disease could not change into another any more than a Hen can breed a Duck he emphasized further that consequently one Sort cannot be a preservative against any other Sort

One of the outstanding experiments of the premicrobial era was carried out by John Hunter (1728 93) who inoculated himself with syphilis using material from a case which he assumed erroneously to be simple gonorrhea In addition to the tragic consequences for his own life Hunter s experiment was responsible for establishing the belief which persisted for many years that gonorrhea and syphilis were the same disease Of great importance also were the writings by Charles White (1728 1813) in 1773 Oliver Wendell Holmes (1809 94) in 1843 and I P Semmelweis (1818 65) in 1846, concerning the role of cleanliness and other practical sanitary methods in the prevention of puerperal sepsis and of blood poisoning from putrid wounds

Agostino Bassi (1773 1856) demonstrated in 1836 that a fungus was the primary cause of a silkworm disease he formulated the germ theory of disease in very explicit terms In 1839 Johann Schonlein showed that the fungus now known as *Achorion schonleinii* is always present in favus and in 1844 *Trichophyton tonsurans* was established as the cause of *herpes tonsurans* The parasitic role of fungi gained wide acceptance through the publication in 1853 of Robin s *Histoire Naturelle des Vegetaux Parasites*

In 1840 the pathologist Jakob Henle (1809 85) drew up a statement of the conditions which would be required to provide proof of a causal relationship between microbes and the diseases of animals and man These conditions are now known as Koch postulates although they do not appear in concise form in the writings of Robert Koch who had been Henle s student

The first convincing experimental observations on a bacterial cause of disease was made by C J Davaine (1812 82) who detected as early as 1850 minute rods which he called infusoria in the blood of sheep dying of anthrax Stimulated by Pasteur Davaine returned to this discovery and described his results in 1864 He transferred the disease to healthy animals by infecting them with blood containing the characteristic rods infection occurred even when the blood was diluted a million times In 1865 J A Villemin (1827 92) showed that tuberculosis also could be transmitted at will by injecting tuberculous matter from tuberculous human beings to animals and from

one tuberculous animal to another From 1865 to 1869 Pasteur turned his attention to pebrine a disease of silkworms and demonstrated its parasitic nature moreover he developed practical control technics based on the detection of the causative protozoon in the tissues of infected worms These technics were so effective that they saved the European silkworm industry which had been threatened with destruction by the protozoon

The most spectacular contribution to the germ theory of disease before 1876 came from the English surgeon Joseph Lister (1827 1912) (Godlee 1918) Lister was familiar with Pasteur s publications on the ubiquitous presence of microbes in the air and on their chemical activities and he postulated that this knowledge might help to explain many of the accidents then so commonly encountered in surgical practice He surmised that the microbes surrounding the patient at the time of operation could fall on open wounds and thus be responsible for putrefaction and sepsis Acting on this theory he made it a practice to spray solutions of phenol around his patients during surgery and thus greatly decreased the rate of fatal infections Lister s achievement opened the way for modern surgery and constitutes unquestionably the first conscious application of the germ theory of disease to an important problem of human medicine

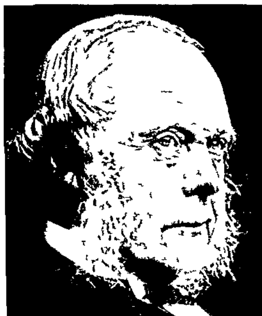

Fig 4 Baron Joseph Lister (1827 1912) (Godlee Lord Lister London Macmillan)

Thus it is certain that infection and microbial etiology were not new concepts when Koch and Pasteur first published their studies on anthrax However these concepts were then ignored or even scornfully rejected by most medical scientists and practicing physicians Even Lister s achievement great though it was did not impress the medical world physicians failed to recognize its relevance to other disease conditions Surprising as it may seem to us the idea that microscopic organisms could cause damage to the body seemed then to be incongruous and contrary to common sense Furthermore the skeptics pointed to the fact that many kinds of microbes are always present in large numbers in the body of healthy men and animals and therefore could not be of great significance in the causation of disease

The great merit of Koch s and Pasteur s experimental studies on anthrax was to prove irrefutably that a certain kind of disease always occurred when a few microbes of the proper kind were introduced into the body and only then Causal relationship was proved by demonstrating that anthrax bacilli which had been made to multiply outside the body for large numbers of generations—in serum urine or broth—retained nevertheless the ability to cause in animals the particular kind of disease with which they had first been found to be associated The validity of the evidence adduced by Koch and Pasteur rested entirely on the exacting nature of the technics they used for isolating the bacteria for cultivating them in pure cultures and for making sure of their identity

Robert Koch s greatness came precisely from the immense skill and ingenuity that he displayed in devising new bacteriologic technics and from the austere discipline with which he applied them to etiologic problems (Bochalli 1954) Suffice it to mention that the plating of cultures on agar surfaces the photomicrography of bacteria and the use of aniline dyes for demonstrating them microscopically were all methods developed in his laboratory

After he had isolated the anthrax bacillus in pure culture and demonstrated its infectivity Koch proceeded to study traumatic infectious diseases and developed methods for the separation of pure cultures from mixed infections (1878 1881) However his most spectacular achievements were the isolation and the cultivation of the tubercle bacillus in 1882 and of the cholera vibrio in 1883 The dramatic character of these diseases and their great prevalence during the 19th century made of Koch a world hero he was treated as a demigod when he traveled to Japan and a shrine was erected in his name

The decades that followed the birth of the germ theory saw the isolation and the characterization of most of the bacterial agents of disease Progress was very rapid because the experimental philosophy and methods developed by Pasteur and Koch were applicable to many types of infections with only minor changes of detail However more profound modifications became necessary when emphasis shifted from bacterial to rickettsial and viral infections Rickettsia and viruses being unable to grow in lifeless media their isolation and cultivation required the development of new methods based chiefly on the use of fertilized eggs and tissue cultures (see the companion volume of this series edited by Tamm and Horsfall)

The era opened by Pasteur Lister and Koch has been properly called the Golden Era of medical microbiology and it probably represents the greatest single contribution so far made to the theory and the practice of medicine There is no doubt that the stimulus to this phenomenal advance was the establishment of the bacterial cause of disease which provided a scientific basis for etiologic diagnosis specific therapy and preventive medicine The profound reformation of medical thought brought about by bacteriologic knowledge was achieved against violent opposition but experimental medicine emerged from the bitter struggle much strengthened and enlarged Experimental microbiology thus constituted more than a useful helping hand to medicine it was the guiding finger as well It wrought such changes in human health that its contributions to human welfare are at least equal to those of any other science Diseases such as typhoid fever diphtheria tuberculosis and pneumonia have been reduced from scourges with a high mortality to manageable conditions surgery was lifted out of the despondency of laudable pus into the safety of asepsis The great epidemics of the past remain a threat only where the required precautions are neglected

THE STRUCTURE AND THE PROPERTIES OF MICROORGANISMS

One of the first tasks faced by medical microbiologists was to devise technics for the cultivation the differentiation and the identification of the agents of disease Much of the microbiologic literature published around the turn of the century deals with the development of selective culture media the definition of physiologic activities (especially the ability to attack various sugars alcohols and amino acids) the manner of growth in broth on agar in gelatin aerobically or anaerobically etc From the scientific point of view this literature is rather dull yet it provided the kind of information on which much of microbiologic taxonomy and etiologic diagnosis still depends today Fortunately a broader kind of knowledge continued to develop along with this prosaic though essential type of information Progressively the study of microbes as living entities moved into the main channels of biologic thought

To the biologist of the 19th century bacteria had first appeared to be so primitive as to be at the very threshold of life Speaking of what he considered the smallest and at the same time the simplest and lowest of all living forms Ferdinand Cohn (1828 98) asserted in 1872 They form the boundary line of life beyond them life does not exist so far at least as our microscopic expedients reach and these are not small The minute dimensions of bacteria were considered by many to be incompatible with any significant morphologic differentiation it encouraged the chemist to treat the bacterial cell as a simple colloidal system and as a bag of enzymes This assumed primitiveness of structure appeared to be confirmed in biochemical terms when Serge Winogradsky (1856 1953) announced in 1887 that cer

tain microorganisms—those of the auto trophic group—could synthesize their proto plasm from mineral salts and carbon dioxide utilizing for the reduction of the latter the energy released by the oxidation of inorganic substances—ammonia nitrites sulfur hy drogen etc Could not this most primitive biochemical expression of life the production of organic matter from inorganic substances be considered as the beginning of *life* on earth?

Cytologic studies were quick to dispel any illusion as to the structural simplicity of bac teria Differential staining reactions studies of sporulation motility osmotic behavior etc revealed the existence in bacteria of various kinds of plasma membranes cell walls capsules intracellular bodies organs of locomotion etc which give to each bac terial type a characteristic complexity Fur thermore the biochemist soon came to rec ognize in microbial life the same type of chemical reactions biocatalysts metabolic channels and products which occur in the highest organisms Even the autotrophic bac teria those primitive beings capable of synthesizing life from the atmosphere and the rock are now known to operate through the same elaborate mechanisms found in the most evolved metabolic types

Many books published during the past 100 years on the structure and the properties of microorganisms make it easy to follow the development of knowledge in this field How ever the most striking impression gained from such a survey is not so much the in crease in amount of knowledge as the quali tative change in attitude The change was compelled by the progressive discovery that microbial life and its role in health and dis ease cannot be understood without consider ation of all aspects of biology—the most de tailed in terms of chemical or genetic analysis as well as the most complex in terms of cel lular and ecologic integration Chapters 3 and 5 of the present volume illustrate the recent growth of knowledge concerning the metabolic and structural complexities of mi croorganisms Chapters 2 and 38 reveal that microorganisms display the widest pos sible range of interrelationships with other living things from destructive parasitism to complete symbiosis—and that these inter relationships have a Darwinian evolutionary basis The knowledge concerning bacterio phage will serve as one example among many others that could have been selected to illustrate that points of view concerning microscopic life continue to change even in our time

The discovery of bacteriophage lysis by d Herelle and Twort appeared at first sight to confront biologists with the most primitive manifestation of life indeed with a phe nomenon in which it seemed that biology and chemistry could no longer be differentiated For a whole generation bacteriophage was considered as a substance to be crystallized and defined by purely chemical methods and the lysis of bacteria that it causes was as sumed to be a straightforward enzymatic process However recent discoveries have shattered these illusions Electron microscopy shows that bacteriophages are viruses with highly complex organizations made up of several morphologic structures each with a different chemical composition and a differ ent function bacterial lysis is the outcome of a complex infectious process during which the viruses multiply at the expense of meta bolic processes in the bacterial cells which they parasitize Bacteriophages can enter into various types of associations with the proper kinds of bacteria destroying them in some cases but also capable of endowing them with new potentialities under other circum stances Finally bacteriophages can mutate and thus undergo hereditary changes akin to evolutionary adaptation Such complexity is of course incompatible with the view that bacteria and bacteriophages are at the threshold of life

Thus two independent trends can be rec ognized in the development of knowledge concerning microorganisms as living entities On the one hand microbial structure and metabolism are being defined in more and more precise chemical terms on the other hand evidence is accumulating that even the smallest microorganism is a highly complex structure and that its living processes involve adaptive responses to the total environment as well as integration with other living things Microbiology has found its way back into general biology Furthermore the extraor dinary plasticity of microorganisms the ra

After he had isolated the anthrax bacillus in pure culture and demonstrated its infectivity Koch proceeded to study traumatic infectious diseases and developed methods for the separation of pure cultures from mixed infections (1878 1881) However his most spectacular achievements were the isolation and the cultivation of the tubercle bacillus in 1882 and of the cholera vibrio in 1883 The dramatic character of these diseases and their great prevalence during the 19th century made of Koch a world hero he was treated as a demigod when he traveled to Japan and a shrine was erected in his name

The decades that followed the birth of the germ theory saw the isolation and the characterization of most of the bacterial agents of disease Progress was very rapid because the experimental philosophy and methods developed by Pasteur and Koch were applicable to many types of infections with only minor changes of detail However more profound modifications became necessary when emphasis shifted from bacterial to rickettsial and viral infections Rickettsia and viruses being unable to grow in lifeless media their isolation and cultivation required the development of new methods based chiefly on the use of fertilized eggs and tissue cultures (see the companion volume of this series edited by Tamm and Horsfall)

The era opened by Pasteur Lister and Koch has been properly called the Golden Era of medical microbiology and it probably represents the greatest single contribution so far made to the theory and the practice of medicine There is no doubt that the stimulus to this phenomenal advance was the establishment of the bacterial cause of disease which provided a scientific basis for etiologic diagnosis specific therapy and preventive medicine The profound reformation of medical thought brought about by bacteriologic knowledge was achieved against violent opposition but experimental medicine emerged from the bitter struggle much strengthened and enlarged Experimental microbiology thus constituted more than a useful helping hand to medicine it was the guiding finger as well It wrought such changes in human health that its contributions to human welfare are at least equal to those of any other science Diseases such as typhoid fever diphtheria tuberculosis and pneumonia have been reduced from scourges with a high mortality to manageable conditions surgery was lifted out of the despondency of laudable pus into the safety of asepsis The great epidemics of the past remain a threat only where the required precautions are neglected

THE STRUCTURE AND THE PROPERTIES OF MICROORGANISMS

One of the first tasks faced by medical microbiologists was to devise technics for the cultivation the differentiation and the identification of the agents of disease Much of the microbiologic literature published around the turn of the century deals with the development of selective culture media the definition of physiologic activities (especially the ability to attack various sugars alcohols and amino acids) the manner of growth in broth on agar in gelatin aerobically or anaerobically etc From the scientific point of view this literature is rather dull yet it provided the kind of information on which much of microbiologic taxonomy and etiologic diagnosis still depends today Fortunately a broader kind of knowledge continued to develop along with this prosaic though essential type of information Progressively the study of microbes as living entities moved into the main channels of biologic thought

To the biologist of the 19th century bacteria had first appeared to be so primitive as to be at the very threshold of life Speaking of what he considered the smallest and at the same time the simplest and lowest of all living forms Ferdinand Cohn (1828 98) asserted in 1872 They form the boundary line of life beyond them life does not exist so far at least as our microscopic expedients reach and these are not small The minute dimensions of bacteria were considered by many to be incompatible with any significant morphologic differentiation it encouraged the chemist to treat the bacterial cell as a simple colloidal system and as a bag of enzymes This assumed primitiveness of structure appeared to be confirmed in biochemical terms when Serge Winogradsky (1856 1953) announced in 1887 that cer

history of medical microbiology because it convinced the medical and the lay public that infectious diseases could be controlled by specific vaccines

Analysis of the mechanisms through which the body develops resistance against infec tion has proceeded along two independent channels One group of studies was focused on the role played by various kinds of tissue cells in resistance to infection another group emphasized in contrast the protective activ ity of blood serum and other humors For many years a violent polemic raged between the protagonists of the cellular theory led by Elie Metchnikoff (1845 1916) and the pro tagonists of the humoral theory led by Emil Behring (1854 1917) and Richard Pfeiffer (1858 1945) Progressively however the truth emerged that cellular and humoral fac tors both play a role and indeed often act jointly The modern position in this regard is presented in Chapter 8 For the sake of convenience it will be helpful to consider separately the development of knowledge concerning the cellular and the humoral mechanisms of defense

Between 1870 and 1877 several patholo gists and microbiologists had reported that bacteria were often seen in the leukocytes of pus they concluded from such observations that these cells provide a suitable lodgement for microorganisms and help them to become distributed throughout the body Metchnikoff placed a radically different interpretation on these facts Observations in invertebrates and vertebrates convinced him that ameboid (mesodermal) cells commonly destroy the microbes that they ingest for this reason he called them phagocytes (devouring cells) and concluded that they protect the body against infection Indeed he came to regard phago cytosis—the scavenging activity of macro phages and microphages—as the most im portant mechanisms of defense (1883) This view was strengthened through the demon stration by Denys and Leclef in 1845 that immunization greatly enhances phagocytic activity

The humoral doctrine arose from the dis covery of toxins and antitoxins Pasteur had first recognized the role of bacterial toxins in infection during his work on fowl cholera (1880) Diphtheria toxin was dis covered and studied by F Loeffler then by

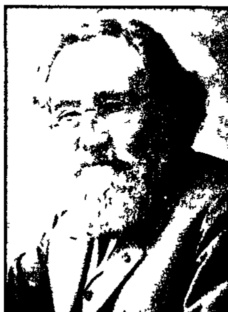

FIG 6 Elie Metchnikoff (1845 1916)

E Roux and A Yersin in 1887 88 and tetanus toxin by Knud Faber in 1890 The same year Behring produced diphtheria anti toxin and then tetanus antitoxin (in associa tion with S Kitasato) Further work by Behring and E Wernicke then by Roux and Martin soon made it possible to treat diph theria in man by antitoxin produced in horses The development by Paul Ehrlich (1854 1915) of methods for the standardiza tion of toxins and antitoxins (1896) pro vided a quantitative basis for therapy and for the analysis of antitoxic action During the late 1880 s and early 1890 s several other findings provided additional support for the humoral doctrine of immunity

It will be noted from the preceding para graph that the fundamental discoveries con cerning toxins and antitoxins were all made within a very few years This rapid accumu lation of new findings has remained to this day a characteristic of the science of humoral immunity—a consequence of the fact that it is much easier to experiment with serum and other body fluids than with living tissue cells A number of discoveries with their respec tive dates will be listed in the following para graph to illustrate further the rapidity with which the new science developed

The bactericidal action of serum for an thrax bacilli was discovered by J Fodor in

FIG 5 Oswald Theodore Avery (1877 1955)

pidity with which they respond to the environment either by hereditary genetic variations or by reversible phenotypic modifications makes them ideal objects for studying some of the problems which are common to all living things It is worth noting here for example that the lifelong dedication of Oswald Theodore Avery (1877 1955) to the study of pneumococci has paved the way for two large developments of modern biologic research namely the immunochemical analysis of cellular structure and the role of deoxyribonucleic acids in the transmission of hereditary characteristics Microbes truly appear as the most versatile tools of the general biologist

THE RESPONSE OF THE BODY TO INFECTION

From the most ancient times and even among extremely primitive people methods have been developed empirically to increase resistance to noxious influences and infectious agents In several tropical countries people expose themselves deliberately to various venoms in order to develop resistance to snake bites the word mithridization recalls that King Mithridates had made it a practice to ingest small amounts of several poisons in order to protect himself from poisoning by his enemies Ancient physicians of the Near East had learned that they could protect young women from the disfiguring effect of Aleppo boils by inoculating them on the thigh early in life with some of the infectious material Variolation the deliberate infection with smallpox under controlled favorable circumstances had been practiced widely in Eastern countries long before the technic was introduced into England in the 18th century The demonstration by E Jenner (1749 1823) in 1796 that resistance to smallpox could be induced by injecting into man material from naturally acquired cowpox was the substantiation of a popular belief The technic came to be called vaccination from vacca the cow and was immediately a triumphant success Wherever it was applied systematically it reduced smallpox from a universal and often fatal disease to a medical rarity

Thus immunization had long been practiced without rational basis but it entered the domain of scientific medicine through *Pasteur s studies on experimental infections* In 1879 Pasteur observed accidentally that chickens which had been inoculated with an old culture of chicken cholera and had failed to develop the disease proved to be resistant when reinfected with a young and highly virulent culture of the same microbe Intuitively he recognized the analogy of this protective effect with that induced by cowpox against smallpox and he referred to the newly discovered phenomenon as vaccination in honor of Jenner Pasteur established the generality of the doctrine of specific immunization by developing vaccines against anthrax in 1881 and against swine erysipelas in 1882 he demonstrated their effectiveness and practical usefulness in spectacular field experiments *However it was his work on* rabies immunization (1888) that gained him international fame Rabies immunization occupies a place of immense importance in the

history of medical microbiology because it convinced the medical and the lay public that infectious diseases could be controlled by specific vaccines

Analysis of the mechanisms through which the body develops resistance against infection has proceeded along two independent channels One group of studies was focused on the role played by various kinds of tissue cells in resistance to infection another group emphasized in contrast the protective activity of blood serum and other humors For many years a violent polemic raged between the protagonists of the cellular theory led by Elie Metchnikoff (1845 1916) and the protagonists of the humoral theory led by Emil Behring (1854 1917) and Richard Pfeiffer (1858 1945) Progressively however the truth emerged that cellular and humoral factors both play a role and indeed often act jointly The modern position in this regard is presented in Chapter 8 For the sake of convenience it will be helpful to consider separately the development of knowledge concerning the cellular and the humoral mechanisms of defense

Between 1870 and 1877 several pathologists and microbiologists had reported that bacteria were often seen in the leukocytes of pus they concluded from such observations that these cells provide a suitable lodgement for microorganisms and help them to become distributed throughout the body Metchnikoff placed a radically different interpretation on these facts Observations in invertebrates and vertebrates convinced him that ameboid (mesodermal) cells commonly destroy the microbes that they ingest for this reason he called them phagocytes (devouring cells) and concluded that they protect the body against infection Indeed he came to regard phagocytosis—the scavenging activity of macrophages and microphages—as the most important mechanisms of defense (1883) This view was strengthened through the demonstration by Denys and Leclef in 1845 that immunization greatly enhances phagocytic activity

It will be noted from the preceding paragraph that the fundamental discoveries concerning toxins and antitoxins were all made within a very few years This rapid accumulation of new findings has remained to this day a characteristic of the science of humoral immunity—a consequence of the fact that it is much easier to experiment with serum and other body fluids than with living tissue cells A number of discoveries with their respective dates will be listed in the following paragraph to illustrate further the rapidity with which the new science developed

The bactericidal action of serum for anthrax bacilli was discovered by J Fodor in

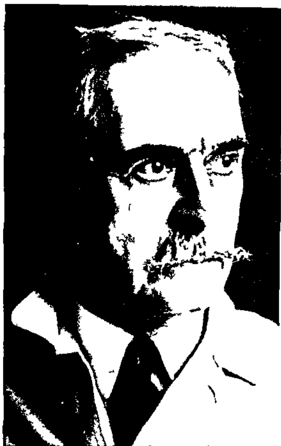

FIG 7 Karl Landsteiner (1868 1943)

1886 complement (alexin) by H Buchner in 1889 the lytic action of immune serum on cholera vibrios by Pfeiffer in 1894

Around the turn of the century an immense number of reports were published describing the acquisition of new activities in the serum of animals immunized with various antigenic materials Only a very few of the representative contributions which thus gave rise to the derivative science of serology can be listed here In 1889 Charrin and Roger noticed that the cells of *B pyocyaneus* growing in immune serum lost their motility and clumped in agglomerated masses Durham (1896) and M Gruber (1897) then showed that such clumping by immune serum occurred specifically for each kind of bacterium Specific agglutination as the phenomenon came to be called soon was applied for diagnostic purposes in particular by F Widal for typhoid In 1898 Jules Bordet (1870 1961) showed that injection of red blood cells into animals also elicited the production of specific aglutinin and this discovery provided Karl Landsteiner (1868 1943) with a technic for the classification of blood groups (1900)

In 1898 Bordet observed that red cells were lysed by antiserum when fresh guinea pig serum (complement) was added to the system This discovery was followed by the recognition of many other examples of immune lysins Bordet and Gengou then demonstrated in 1901 that complement was removed or fixed in the course of serologic reactions and they worked out the complement fixation test as the most delicate technic for the detection of antigen antibody reactions In 1906 Wassermann Neisser and Bruck applied this technic to the serodiagnosis of syphilis

In 1897 Kraus observed that addition of specific antiserum to a clear filtrate of cholera vibrio culture resulted in the rapid production of a fine precipitate which aggregated into flocculi and settled to the bottom of the tube Similar findings were made with filtrates of cultures of typhoid and plague bacilli and the reaction proved to be highly specific to the kind of bacterium The serum components responsible for the reactions were called precipitins Furthermore it was soon found that highly specific precipitins could be produced not only for bacterial filtrates but also for many other organic substances especially proteins and polysaccharides The precipitin reaction was applied by Nuttal to the study of phylogenic relationships between mammalian species (1902 04) it permitted the serologic identification of blood stains and of adulterants in food needless to say it provided also a valuable tool for the analysis of immune processes

The first evidence of allergic reactions came from the discovery of tuberculin by Robert Koch in 1890 Koch s claim that tuberculin was useful in the treatment of tuberculosis proved to be erroneous nevertheless the tuberculin reaction turned out to be of immense importance as a highly specific diagnostic test of tuberculous infection In addition it became the prototype of the delayed type of allergy In rapid steps the field of allergy broadened through the discovery of anaphylaxis (Portier and Richet 1902)

of the Arthus reaction (Arthus and Breton 1903) of serum disease (von Pirquet and Schick 1905) and of the Prausnitz Kustner reaction (1921)

For a while agglutinins precipitins lysins and allergins were regarded as different substances elicited by the antigenic stimulus As was remarked facetiously every time an immunologist discovered a new phenomenon he attributed it to a new phenominin In reality however it soon became apparent that all immunologic phenomena had a similar chemical basis and that their specificity is due to some change in the body cells or serum constituents which make them fit the molecular structure of the respective antigen Paul Ehrlich was the first to formulate a theory accounting for these facts From his student days he had been obsessed with the belief that the selective staining of tissues by various dyes was an expression of chemical affinity he carried this line of thought into his analysis of the specific interactions between antigens and antibodies and into his formulation of the side chain theory and finally as we shall see later into his search for chemotherapeutic agents

The side chain theory was a pictorial as well as picturesque expression of the lock and key relationship which governs the chemical affinity between antigen and antibody Bordet elaborated on this theory by pointing out that while the specific adsorption of antigen or antibody had a chemical basis the final effects of the reaction were produced by a nonspecific action of electrolytes and a shift of electrical charges In 1907 S Arrhenius and T Madsen postulated that the antigen antibody reaction behaved as a *reversible reaction analogous to that between weak acid and weak base* and they concluded that free antigen free antibody and antigen antibody complex could coexist in the same mixture

The precise chemical formulation of immunologic specificity emerged from the monumental studies of Karl Landsteiner (1868 1943) whose classic monograph *The Specificity of Serological Reactions* (1944) gave its modern philosophy to the field The quantitative analysis of serologic reactions began with Ehrlich s standardization of toxin and antitoxin (1896) it was extended through the finding by Dean and Webb (1926) that antigen and antibody react in terms of relative proportions more or less independent of absolute concentrations This quantitative approach reached its now classic form in the studies of Michael Heidelberger who showed that mass action formulae can be developed for many types of serologic reactions

The complex nature of complement and the mechanism of its action are other aspects of immunologic science which are still in the process of definition (see Chaps 8 and 9) Finally it should be mentioned that the participation of neurohumoral mechanisms in immune processes has been emphasized by a few Russian workers but constitutes a field which is almost completely neglected at the present time

Each of the immunologic phenomena which have been mentioned has been used in the study of the constituents and products of the microbial agents of disease the main results of such antigenic analysis are described in the chapters of this book devoted to the various microbial groups Except in a few cases the analysis of in vitro serologic reactions has failed to provide a complete understanding of the processes which increase the resistance of the body to infection *Antitoxic immunity and the enhancement of* phagocytosis of pneumococci by antibodies directed against their capsular polysaccharides constitute clear and well worked-out examples of humoral immunity In contrast understanding of the mechanisms through which cells destroy the microorganisms that they engulf has not grown much since Metchnikoff s time indeed there is still much *doubt that cellular immunity really exists* as an independent entity

THE BIRTH OF CHEMOTHERAPY

As in the case of immunization many empirical methods had been developed for disinfecting contaminated materials and even for treating some microbial diseases long before the advent of the germ theory Thus fire quick lime and various kinds of fumigations have long been used for the purification of air or objects assumed to be contaminated Ipecacuanha root (containing

emetine) was considered as a specific in the treatment of dysentery before its effectiveness in amebiasis had been proved and especially cinchona bark (containing quinine) has been the standard remedy for malaria (as well as for other fevers) since it was introduced from South America in the 17th century Between 1750 and 1752 John Pringle presented before the Royal Society of London several papers describing Experiments Upon Septic and Antiseptic Substances thus introducing the term *antiseptic* into the scientific literature However as already mentioned the first *conscious* application of antisepsis based on the germ theory of disease was the use of phenol sprays by Lister in his surgical practice

The modern chemical theory of disinfection and chemotherapy has its origin in the experimental studies of Paul Ehrlich between 1905 and 1915 His biochemical approach was an extension of his views on antigen antibody reaction and can be summarized by two of his most famous aphorisms

> Only such substances can be anchored at any particular part of the organism which fit into the molecule of the recipient combination as a piece of mosaic fits into a certain pattern
>
> Antitoxins and antibacterial substances are so to speak charmed bullets which strike only those objects for whose destruction they have been produced

Fig 8 Paul Ehrlich (1854 1915) (*Marquardt* Paul Ehrlich Deutsche Verlags Anstalt)

Ehrlich was obsessed with the belief that there must exist synthetic chemicals which like dyes and antibodies have a selective affinity for and hence a selective action on parasitic cells (*nihil agit nisi fixatur*) This selective chemical approach led him to the development of several drugs useful in the treatment of protozoal and spirochetal diseases The best known of these is the organic arsenical arsphenamine (salvarsan) which under the name of 606 reigned supreme in the treatment of syphilis until the introduction of penicillin Ehrlich failed in his attempts to discover the magic bullet which would be so specific for the microbes to be attacked that it would not damage tissue cells nor was he successful in developing drugs active against the true bacterial rickettsial and viral infections Nevertheless there is no doubt that his work constitutes even today the most visionary and rational approach to chemotherapy

The first drug to prove to be effective in the treatment of bacterial infections was the dye Protonsil which was first used by Foerster for the treatment of experimental streptococcal infection and was formally introduced by Domagk (1935) of the I G Farben industry in Germany At the Pasteur Institute in Paris Trefouel soon discovered that the effective agent in Protonsil is not the dye itself (which by the way is completely inactive in vitro) but its simple cleavage product sulfanilamide Thus was opened the chemotherapeutic era and the possibility of synthesizing many derivatives of sulfanilamide clinically superior to the initial product The discovery by Woods in 1940 that sulfanilamide acts by interfering with the utilization of the essential growth factor para aminobenzoic acid led to the theory that metabolic competitive inhibition is the basis of drug action It appeared then and may still be true that the search for antimetabolites constitutes the most rational approach to the discovery of antibacterial drugs In fact

however the greatest therapeutic advances have come from another approach less well defined chemically and indeed almost empirical but more effective in practice

In 1877 Pasteur had observed that cultures of anthrax bacilli often died after becoming contaminated with soil bacteria and he suggested that this might have useful implications for the development of therapeutic agents Many observations have since confirmed that certain microbial products are toxic for various microbial species One of these was made by Alexander Fleming (1881 1955) who noticed in 1929 that an extract of a certain Penicillium had powerful antibacterial properties (see biography by A Maurois 1959) Fleming named the active material penicillin but he could neither purify it nor obtain it in quantities sufficiently large for therapeutic assays In 1939 R Dubos developed a general technic which permitted the systematic search for antimicrobial agents among saprophytic organisms It led to the isolation from a soil bacterium of an antibacterial agent tyrothricin which was active in the treatment of experimental infections in mice The active material proved to be a polypeptide (gramicidin) which was crystallized produced commercially and used in the treatment of infected wounds and of bovine mastitis however its toxicity precluded its use in systemic infections In 1940 H W Florey and E Chain succeeded in preparing Fleming s penicillin in a stable form crystallized it and demonstrated its phenomenal effectiveness in vivo as well as its lack of toxicity Thus began a new era in antibacterial therapy which was marked by the discovery in rapid succession of several highly effective drugs obtained from molds and actinomycetes Streptomycin discovered by S A Waksman in 1944 deserves a special mention here because it proved to be highly effective in the treatment of tuberculosis

The enthusiasm created by the discovery of sulfanilamide penicillin and other antibacterial drugs was so great that many physicians and scientists were led to believe that the conquest of infectious disease had finally been achieved Soon however it became evident that several fundamental and probably inescapable difficulties stand in the way of eradication of disease by drugs Most microbes readily develop mutant forms which are drug resistant and it is proving difficult to discover new drugs fast enough to cope with this situation Even more important *however is the fact that many microbial* forms persist in a dormant state in the tissues even after successful therapy The problem of the persisters is as disturbing for the student of chemotherapy as the existence of the carrier state is for the student of epidemiology

Fig 9 Sir Alexander Fleming (1881 1955) (Vogue 1953 Conde Nast Publications)

THE EVOLUTION OF EPIDEMIOLOGIC THOUGHT

All ancient leaders of roaming tribes and conquering armies had to enact sanitary regulations in order to check the spread of

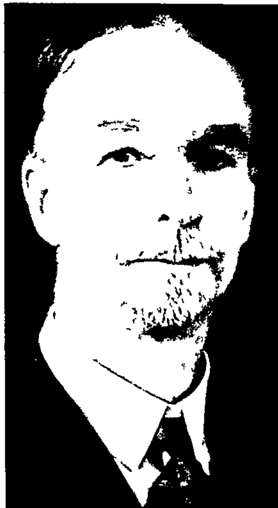

FIG 10 Theobald Smith (1859 1934)

filth diseases Thus Moses formulated strict regulations for camp life before leading his people across the desert In the words of the medical historian Garrison The ancient Hebrews were the founders of prophylaxis and their high priests were true medical police The admonitions in Leviticus the various forms of taboos and quarantines found in all civilizations and the segregation of lepers during the Middle Ages are only a few of the many examples proving that practical men have long realized empirically that many diseases are communicable and that the best protection against them is to prevent their spread

The enormous shifts of people brought about by the Industrial Revolution and the attendant crowding in the filthy tenements of the mushrooming cities created conditions favorable for the spread of infectious diseases during the 19th century The prevalence of epidemics stimulated important epidemiologic studies which led to highly effective control practices even before the pathogenic role of microbes had been convincingly established The few classic examples now to be mentioned should be considered only as illustrations of the many facts which were established during the premicrobial era

In 1854 the cholera epidemic in London provided John Snow (1813 58) with the opportunity for a spectacular demonstration that water constitutes the vehicle through which this disease is transmitted Within 250 yards from the spot in Broad Street where the outbreak began there were 500 deaths from cholera in 10 days With unerring exactitude Snow traced the outbreak to a particular pump in Broad Street and found evidence that its water was contaminated with organic matter Even though he knew nothing of cholera vibrios he thus demonstrated that cholera was water borne and he stopped the epidemic so the story goes by removing the handle from the pump William Budd (1811 80) also provided convincing evidence that typhoid is transmitted by the excreta of the patient again without the benefit of bacteriologic knowledge In Munich Max von Pettenkofer (1818 1901) went far toward ridding his city of typhoid fever simply by cleaning it up and providing it with pure water brought directly from the mountains And similarly Florence Nightingale (1820 1910) effected her reforms of hospital sanitation simply through common sense practices and through her belief in pure air pure water and cleanliness

Florence Nightingale as well as von Pettenkofer remained to the end indifferent and even hostile to the germ theory of disease therefore it is of particular interest that they were so highly effective in combating infection Countless similar examples could be quoted to illustrate that shrewd epidemiologic observations and the development of valuable sanitary practices are not entirely dependent on bacteriologic knowledge The control of malaria and of yellow fever

through environmental changes which eliminated mosquitoes constitutes other examples of medical achievements based on epidemiologic rather than etiologic understanding

Needless to say epidemiologic analysis became much easier and more precise when it could be based on knowledge of causative agents One needs only mention as example the demonstration by A Gartner in 1888 that an outbreak of food poisoning in a human population had been caused by *Salmonella enteritidis* which had contaminated the meat of a sick cow—a finding which provided the pattern for the study of human disease a sociated with animal infections The control of water borne typhoid became much easier and more dependable after Theobald Smith (1859 1934) had shown in 1892 that the enumeration of coliforms in water provides a useful index of fecal contamination Worth mentioning also is the demonstration by Theobald Smith and J Ravenel that bovine tuberculosis can be transmitted to human beings for example through contaminated milk A very large chapter could be written on the enormous practical importance of the demonstration that many protozoan bacterial rickettsial and viral diseases are transmitted by insects Plague rodents and their fleas have played a large part in the history of mankind and their interrelationships became clear only in the early years of the 20th century Hans Zinsser made typhus the topic of a best seller as well as of a fascinating account of human epidemiology in his famous books *Rats Lice and History*

Progressively the knowledge concerning microbes their vectors of transmission the factors which affect their spread and the susceptibility of human populations to them became so extensive that epidemiologists found it possible to describe the course of epidemics in mathematical terms In several cases indeed the shape of the epidemic curves proved to be almost predictable for each type of infection Epidemiology thus progressed from qualitative and descriptive knowledge to the status of a quantitative science However it is becoming apparent that the greatest difficulties in the understanding of epidemics and in the prediction of their course come not so much from a *quantitative* as from a *qualitative* deficiency of knowledge Some of these deficiencies deserve mention here because they point to areas of ignorance which must be explored before further progress can be made in understanding the determinants of infection and of epidemics

Direct transmission from patient to patient or indirectly through insect vectors water food and fomites accounts for only part of the spread of disease One of the most obscure and important aspects of epidemiology is the persistence in healthy persons of pathogens which can initiate disease processes under ill defined conditions The persistence of diphtheria bacilli in patients who had completely recovered was demonstrated as early as 1890 by E Roux A Yersin and F Loeffler And ever since the existence of carriers has been recognized in practically every type of infection Typhoid Mary is only the symbol of a type of latent infection which occurs not only in typhoid fever but also in countless other infectious diseases as well Furthermore the problem has become still more complicated during recent years by the discovery that persisters commonly resist even the most vigorous forms of chemotherapy It is now realized that many potential pathogens are widely distributed through the community yet they give rise to overt disease only under special conditions As a result of this awareness there is developing an increasing preoccupation with the factors which convert infection into disease In other words interest in the properties of the microbial agents of disease is being supplemented by a lively concern with the genetic hormonal metabolic and *nutritional factors of the host which affect* his resistance to infection The essays by Theobald Smith (1934) and N H Swellengrebel (1939) are representative of this change of emphasis

The significance attached to the expression crowd diseases illustrates well the shift of emphasis from the microbe itself to the host response Until recent years students of infection had only a one sided view of crowd diseases They took it for granted that crowding brings about an increase in infectious disease simply because it facilitates the transmission of pathogens from one per on to the

other However observations on animals and man have now revealed that crowding profoundly affects physiologic processes even in the absence of infection for example it increases the activity of certain hormonal systems and disturbs certain metabolic functions In consequence crowding can increase the prevalence and the severity of infection not only by facilitating the transmission of pathogens but also by decreasing host resistance to them

RETROSPECTIVE AND PROSPECTIVE

The history of medical microbiology thus provides a striking support for the view that the development of science occurs according to a dialectic pattern Until the 19th century the medical scene was dominated by the Hippocratic doctrine infectious disease was regarded primarily as the consequence of some failure in the host After 1880 it appeared that all infectious processes could be accounted for by purely microbiologic explanations—in terms of types numbers properties and structures of the invading pathogens Today attempts are being made to integrate these two attitudes into an ecologic doctrine which would be the synthesis of the physiologic thesis and the microbial antithesis

In fact the ecologic doctrine is making it clear that the problem of infectious disease involves more than the interplay between the pathogen and the individual host Epidemics are phenomena which cannot be understood only from the happenings in individual patients they must be studied at the population level The response of a group to infection exhibits characteristics which are less the expression of the individual members of the group than of the interplay between them In most cases for example the course of tuberculosis can be understood only by regarding the disease as a social phenomenon The past and present history of the group determines the manner of its response to the tubercle bacillus and tuberculous infection in turn affects the behavior of the group as a whole (Dubos and Dubos 1952)

Man does not and could not live in a biologic vacuum Microorganisms are an inevitable part of his environment His response to them is conditioned by his ways of life and on the other hand the effects of microbes on him are so varied and so great that they affect the structure of his societies To be fully comprehended medical microbiology must be considered as an ecologic science

The Evolution of Microbial Diseases

THE SO CALLED CONQUEST OF MICROBIAL DISEASES

By the 1950 s the most optimistic dreams of the founders of medical microbiology had been essentially fulfilled in several countries of Western civilization A very large percentage of the microbial agents of disease had been isolated identified and cultivated in artificial media or in tissue cultures bacteriologic purity of the food and water supplies had become possible through technologic advances practical procedures had been worked out for the large scale production of killed or attenuated vaccines highly effective drugs had become available for the treatment of bacterial and parasitic infections a variety of pesticides had been synthesized and had proved their usefulness for the control of insect vectors

In many places economic prosperity and social organization have now made it possible to take full advantage of the extraordinary scientific achievements of the microbiologic era As a result the mortality rates of infectious diseases have been brought down to a very low level particularly among children and young adults As a result the life expectancy at birth has soared to unprecedented high levels

Therefore most clinicians public health officers epidemiologists and microbiologists felt justified in proclaiming during the 1950 s that the conquest of infectious diseases had finally been achieved Surprising enough this euphoria has not yet been dampened by the increasing awareness that the morbidity rates of infection have not decreased significantly and in some cases have actually increased Despite so much oratory on the conquest of microbial diseases the paradox is that the percentage of hospital beds occupied by patients suffering from infection is now as high as it was 50 years ago Today as in the past disorders of the respiratory and the digestive tracts with a microbial etiology constitute the most frequent causes of absenteeism from school office factory or from training in the Armed Forces

There is a widespread tendency to explain away the fact that infection remains a major cause of disease by invoking the emergence of drug resistant forms of bacteria the appearance of new strains of pathogenic agents and the failure to apply with sufficient vigor the existing knowledge of prophylaxis and therapy In reality however these explanations deal with only minor aspects of the problems The more important reason for the stubborn persistence of infection lies in obscure phenomena concerning the interrelationships between man and his biologic environment As we shall see there are important aspects of the infectious problem which are not controlled by sanitation vaccines or drugs (Dubos 1965)

The point at issue is that the microbial diseases which account for the greatest morbidity in our communities today are completely different in their origin and manifestations from those which are dealt with so effectively by modern technics For this rea

son they will require programs of study and of control different from those which have been emphasized so far The real problem is not how to apply more effectively the control procedures that we already possess or how to improve them but rather to search for a qualitatively different kind of knowledge

The sciences concerned with microbial diseases have developed almost exclusively from the study of acute or semiacute infectious processes caused by virulent microorganisms acquired through exposure to an exogenous source of infection In contrast the microbial diseases most common in our communities today arise from the activities of microorganisms which are ubiquitous in the environment which persist in the body without causing any obvious harm under ordinary circumstances and exert pathologic effects only when the infected person is under conditions of physiologic stress In such a type of microbial disease the event of infection is of less importance than the hidden manifestations of the smoldering infectious process and than the physiologic disturbances which convert latent infection into overt symptoms and pathology This is the reason why the orthodox methods based on the classic doctrines of epidemiology immunology and chemotherapy are not sufficient to deal with the problem of endogenous diseases The need is to develop procedures for re establishing the state of equilibrium between host and parasite

The problems posed by microbial diseases of endogenous origin cannot be stated properly without some historical considerations of the changes in virulence that infectious agents have undergone in the course of time From this point of view as we shall see it is not very enlightening to say of a particular microorganism that it has a high or a low virulence A more meaningful statement is that a given pathogen is generally highly destructive in a given population when the two components of the system first come into contact and that the severity of the infectious process tends to decrease as contact between population and pathogen is continued over several generations In other words the problem of virulence cannot be stated without historical perspective

HISTORICAL CHANGES IN INCIDENCE AND SEVERITY OF VARIOUS MICROBIAL DISEASES

History provides many examples of the fact that social misery and its usual consequence physiologic misery is commonly associated with increase in the prevalence and the severity of microbial diseases War famine and pestilence have been known to ride together throughout history

In many cases of course the infectious diseases associated with crowding or war are directly the result of increased contact with particular types of microbial agents Armies in the field have been plagued by typhoid and dysentery whenever the breakdown of sanitary practices has permitted massive infection with salmonellae and shigellae Napoleon s troops contracted typhus when they were heavily exposed to lice and rickettsia in Eastern Europe during the 1812 Russian campaign Similarly the Western allies suffered much from scrub typhus and malaria in the Asiatic theater during World War II even though the adult native populations with whom they were in contact suffered much less from these diseases to which they had been exposed throughout life

Of equal importance and greater interest perhaps is the fact that crowding wars and social upheavals can increase the prevalence of microbial disease through other mechanisms namely by creating conditions which decrease the general resistance of the body

The tuberculosis epidemic which prevailed throughout the Western World during the 19th century owed part at least of its severity to the long working hours the poor nutrition and the low living standards prevailing among the labor classes during the Industrial Revolution As living standards improved tuberculosis mortality immediately began to decrease The improvement was already noticeable at the end of the century long before any specific measure of prophylaxis or therapy had been introduced Tuberculosis mortality again exhibited a sharp and sudden rise in parts of Europe during World Wars I and II and once more it resumed its downward course as soon as the hostilities were over

During the 1920 s inflation in Germany

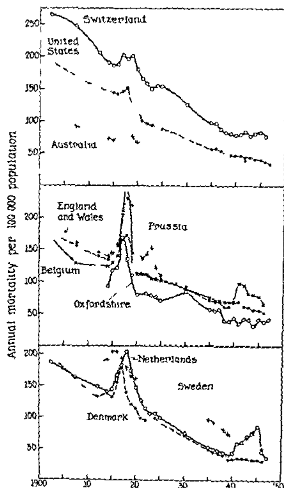

Fig 1 The effect of war on tuberculosis The figures at the bottom indicate the years those at the left the number of deaths per year per 100 000 population (Dubos & Dubos 1952)

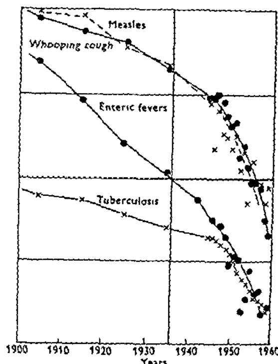

Fig 2 Shows the trend of mortality from some infectious diseases in England and Wales during the 20th century Relative death rates are shown for measles whooping cough enteric fevers and tuberculosis The absolute scales differ but all are shown logarithmically the horizontal lines indicating a 10 fold difference Between 1936 and 1960 there has been almost a *100 fold* diminution in the deaths from whooping cough and measles (Burnet F M Natural History of Infectious Disease ed 3 Cambridge University Press 1962)

provided a spectacular illustration of the bearing of social factors on resistance to disease Following an abrupt fall at the end of the war the tuberculosis mortality increased sharply during the years of inflation and fell again as soon as stabilization of the currency allowed a return to more normal living conditions The rapid and reversible *manner in* which the social body responds to changes *in the social structure* by changes in tuberculosis mortality rates cannot be explained in terms of infection rates The more likely explanation is that large numbers of persons in our communities are in a state of unsteady equilibrium with tubercle *bacilli as well as with many other pathogens and that this* equilibrium is upset whenever disturbances impair the general state of resistance of the body (Dubos and Dubos 1952)

This relationship has been brought out in an analysis of the disease problems in German concentration camps during World War II *Among infectious diseases it was not the* exotic unusual epidemics like typhus cholera or even bacillary dysentery which proved to be the most troublesome in the camps but rather ordinary skin ailments colds bronchopneumonias staphylococcal infections pulmonary tuberculosis—in other *words the type of diseases minor or severe*

caused by microorganisms *endemic* in the normal European communities (Larsen *et al* 1952) Here again increase in con tact infections could hardly account for the aggravation of these endemic diseases Far more important certainly was the loss of natural resistance caused by malnutrition and other forms of physiologic misery It was remarkable indeed that most of the internees overcame their microbial maladies shortly after their return to a normal environment often without the help of specific therapy Even in the case of tuberculosis rapid re covery was the rule though no antimyco bacterial agent was available for treatment of the disease until the late 1940 s

The spectacular decrease in the mortality caused by certain microbial diseases in our communities is due in part to methods of prevention and therapy but in part only Im portant though it has been the effect of these methods does not explain the changes which have occurred during the past century The spectacular health improvements which have recently occurred in Puerto Rico illustrate well that the evaluation of the role played by control programs is complicated by a number of unresolved epidemiologic puzzles

As late as 1950 diarrhea and enteritis were listed as the leading causes of death in Puerto Rico with a mortality rate of 138 for 100 000 population This rate had fallen to 33 in 1962[1] The reasons for this startling change are obscure since the fundamental cause of most intestinal disorders is still today a matter for speculation and since neither antimicrobial vaccines nor drugs could have been used for prophylaxis or treatment During the same period the mor tality from measles whooping cough and scarlet fever has also been reduced drasti cally again without the benefit of specific methods of prophylaxis or treatment

These epidemiologic puzzles are not peculiar to Puerto Rico Thus the mortality from tuberculosis from various diseases of the respiratory and the digestive tracts and especially from viral infections began to fall precipitously in Europe and in the U S A long before the development let alone the use of specific methods of control (Dubos and Dubos 1952 Burnet 1962) (Figs 1 and 2) Granted that the hereditary levels of innate resistance and susceptibility may differ from one national group to another the evolution of the microbial diseases of man strongly suggest that these character istics are not necessarily of racial origin Usually they are rather the consequence of the extent and the duration of the contact that a particular group of people has had with a particular microbial agent The history of disease among the various Indian and Polynesian populations is instructive in this regard

Smallpox is thought to have been intro duced into the American continent early during the Spanish Conquest probably by a Negro in Cortez band The Indians proved to be highly susceptible to the disease which almo t wiped out some of their settlements and there is reason to believe that this dis aster contributed to their rapid defeat by the Spaniards The conquest of North America a century later provided further dramatic evidence of the susceptibility of the Amer indians to smallpox Repeated outbreaks decimated village after village and at times whole tribes Early in the 17th century for example the Massachusetts and the Narra gansett Indians were reduced from presmall pox populations of 30 000 and 9 000 re spectively to less than 1 000 in a few years In the epidemic of 1837 the Mandan popu lation fell from 1 600 to 30 the Assiniboins lost whole villages the Crows one third of their population while the total deaths among the Plains tribes amounted to 10 000 in a few weeks Similar outbreaks occurred as late as 1870 71 among the Blackfeet

Other microbial diseases brought in by the European invaders contributed still further to the rapid decline of the Indian populations during the 19th century There were more than 700 000 Indians in North America before the arrival of the Europeans but only 250 000 in 1850 Tuberculosis played a large part in this holocaust as illustrated by the epidemics which decimated the Plains Indians of Western Canada In the 1890 s the death rate from tuberculosis in the Qu Appelle Valley reservation of Sas katchewan reached the fantastic figure of 9 000 per 100 000 population per year[1] More than half the families of this tribe were eliminated in the first 3 generations of the

epidemic Some 20 per cent of the deaths in the surviving families were caused by tuberculosis! (Ferguson 1955)

Microbial diseases among the Polynesians during the past century present a picture similar to that seen among the Amerindians The South Pacific was explored during the second half of the 18th century Granted that the charm of the Pacific Islands and the amorous welcome of their women may have warped the judgment of the European visitors there is no reason to doubt the validity of their unanimous opinion concerning the health and the vigor of the Polynesian people at that time The Europeans saw throughout the Islands robust and happy men and women obviously well adapted to their physical environment as well as to their local pathogens Yet microbial diseases became rampant among the South Sea islanders within a short time after these early explorations and the Polynesian population soon began to fall From approximately 300 000 at the time of Captain Cook s first visit in 1778 the population of native Hawaiians had fallen to 37 000 in 1860 During the same period the population of the New Hebrides was reduced to one tenth of its original size

There is no doubt that this catastrophe was brought about largely by venereal diseases tuberculosis scarlet fever measles and other infectious disorders that the Polynesians contracted during their short contacts with the Europeans When measles was introduced into Hawaii practically the whole population went down with the disease and many thousands died Epidemics of measles pertussis and influenza occurred again in 1848 and every child born that year died When smallpox struck in 1853 there were over 9 000 cases with 6 000 deaths out of a population of 70 000 During his second and third visits to the South Pacific Captain Cook himself was much disturbed at the thought that his sailors were responsible for having introduced venereal diseases among the Polynesians in Tahiti However he found solace in the belief that the initial guilt was to be placed on Bougainville s French crew who had preceded them

Many other epidemic outbreaks of disease could be selected to illustrate the destructiveness which viruses bacteria and protozoa often exhibit when first introduced into a population In Europe, plague caused a fantastic mortality during the Justinian era and again during the Renaissance The sweating sickness that suddenly struck certain areas of England in Tudor times also proved to be disastrous as can be judged from Caius classic treatise A Boke or Counseill Against the Disease Commonly Called the Sweate or Sweatying Sicknesse

The fact that a disease commonly exhibits extreme virulence when newly introduced into a population was once more illustrated in a dramatic manner by the outbreak of measles in 1952 among the Eskimos of the Canadian Arctic The attack rate in this instance was over 99 per cent, including all ages and the mortality rate reached up to 7 per cent at Ungava Bay An outbreak of poliomyelitis among a group of Eskimos of the Hudson Bay in 1949 exhibited the same pattern Fourteen per cent of the population died, and over 40 per cent developed paralytic disease In this case again all age groups were involved the lowest clinical attack rate being in the infants

Still another example made familiar by the writings of Albert Schweitzer is provided by African trypanosomiasis also known as sleeping sickness Trypanosomiasis was introduced in the Ogowe region of Equatorial Africa some 40 years ago by carriers that came with the Europeans from Loango where it apparently has existed from time immemorial The disease proved to be terribly destructive in its new territory carrying off one third of the population in the course of a few years In Uganda it killed 200 000 persons out of 300 000 in 6 years Of the 2 000 inhabitants in a village of the Upper Ogowe only 500 survived after 2 years of the epidemic

The examples cited above—and these are only a few among many others that would tell the same story—leave no doubt that whole populations can be literally decimated by pathogens with which they have had little contact in the past It is apparent on the other hand that the diseases introduced by the white man among the Indians the Polynesians and other primitive people during the 18th and the 19th centuries no longer

affect them as acutely and with as rapid a fatal outcome as was uniformly the case in the past These people have developed or are developing biologic responses to infection which are similar to those seen in the Western world under normal conditions

The high mortality rates caused by the plague bacillus or by the yellow fever virus among Europeans probably can serve as an analogy for the degree of virulence that the tubercle bacillus or the measles virus had for the Polynesians or the Indians 2 centuries ago Tuberculosis and measles are still important causes of disease among these people today, but as already mentioned they rarely give rise to catastrophic epidemics in the areas where they have been established for several generations Similarly it has been observed that after a while African trypanosomiasis loses some of the destructive character that it exhibited when first introduced into new districts of Equatorial Africa The disease lingers on but it carries off small numbers of victims instead of killing two thirds of the exposed populations as it once did

Precise observations are available concerning the changes in the clinical manifestations of tuberculosis among some Indian tribes of North America In the first and the second generations to suffer from the tuberculosis epidemic in the Qu Appelle Valley reservation extensive glandular involvement was the rule in school age children Meningitis generalized miliary disease and bone and joint disease were extremely frequent—evidence of inability of the host to localize infection In 1921 at a time when the generalized epidemic was in the third generation the disease showed a greater tendency to localize in the lung and to exhibit a chronic course the mortality was falling and glandular involvement had dropped to 7 per cent among school children This latter manifestation of high susceptibility to tuberculosis has continued to decline steadily and was seen in less than 1 per cent of children in the 4th generation In other words while tuberculosis among the Amerindians exhibited at first a very acute course different in character from that observed in people who have had contact with the tubercle bacillus for several generations now it is undergoing a change which makes it resemble the more chronic type of disease commonly seen among Western people under normal conditions (Ferguson 1955)

EXOGENOUS VERSUS ENDOGENOUS MICROBIAL DISEASE

Irrespective of the specific nature of their etiologic agents and of their pathologic manifestations microbial diseases can have two different kinds of origin They can be either exogenous or endogenous

Many pathologic processes are of course the direct outcome of exposure to a virulent pathogen Smallpox yellow fever typhus syphilis diphtheria tuberculosis typhoid fever malaria etc illustrate situations in which the disease can usually be traced to a well-defined exposure to the responsible microbial agent the pathologic phenomena then usually develop within a fairly predictable period of time after exposure This truly *infectious* kind of microbial disease with an *exogenous* origin is still of immense importance throughout the world but it has become less of a menace in our own communities thanks to public health practices vaccination prompt diagnosis and antimicrobial therapy

In contrast the microbial diseases which are now gaining prominence especially in the prosperous countries of the Western world are often caused by microbes formerly regarded as essentially harmless for example the coliform and other gram negative bacilli the nonhemolytic streptococci various kinds of yeasts as well as fungi and probably many viruses still unidentified Even though their virulence is low nevertheless these organisms can give rise to serious pathologic states under special physiologic circumstances

The expression *endogenous* microbial disease refers to any pathologic state caused by microorganisms acquired at some prior time which have persisted in the body as part of its indigenous microbiota (see Chap 14) However it is important to emphasize that highly virulent pathogens such as tubercle bacilli can also act as etiologic agents of endogenous disease The reason is that most types of virulent organisms if not all can become established in the body and persist

in it without manifesting their presence in the form of overt disease until the general resistance of the host is lowered

Endogenous microbial diseases have always been responsible for a very large amount of human misery but two developments have increased their relative importance and made them more obvious during recent years One is that the exogenous infectious processes are increasingly being brought under control a situation which has made it easier to recognize the microbial diseases of endogenous origin The other development is that paradoxically enough many therapeutic procedures introduced by modern scientific medicine favor the proliferation of certain components of the indigenous flora and thus allow them to cause disease For example enteritis caused by staphylococci yeasts or fungi frequently occurs when the normal intestinal ecology is disturbed by the administration of antimicrobial drugs Similarly the microorganisms of the indigenous flora often proliferate after treatment with corti one or antileukemic drugs as well as following certain surgical procedures such as subtotal gastrectomy

Awareness of the fact that most pathogens are widely distributed and yet do not cause clinical disease except in a very small percentage of persons and animals harboring them has come chiefly from the study of latent viral and rickettsial infections However latent infections with virulent bacteria fungi and higher parasites are in fact at least as common as are those with viruses and rickettsia Surveys made in different parts of the world show for example that 30 to 50 per cent of normal persons harbor coagulase positive staphylococci in their nasopharynx

Until a few years ago practically all human beings in the Western world did become infected with tubercle bacilli and this situation still exists today in most underprivileged countries yet only a small percentage of tuberculin positive persons develop clinical tuberculosis In the United States *Amoeba histolytica* can be isolated from the stools of a surprisingly large number of persons who have never suffered from amebiasis Similarly some 30 per cent of the population give a positive skin test for toxoplasmosis and encysted trichina are often found in muscles in the absence of any clinical sign of trichinosis Indeed the list of latent infections with all classes of pathogens continues to grow as the search for them is expanded

A few examples taken from the fields of animal and human pathology will illustrate how endogenous diseases manifest themselves under natural conditions

Shipping fever also known as transit fever is a severe disease which strikes farm animals when they are moved from one area to another under conditions of stress the disease is caused by a great variety of microbial agents Calves, for example commonly develop pneumonia or enteritis during transit and pigs become susceptible to the pathologic effects of *Erysipelothrix* which they carry in a latent state (Francis 1959) Interestingly enough, most of the manifestations of shipping fever can be prevented by treating the animals with tranquilizers at the time of shipment In some unexplained manner these drugs minimize the physiologic disturbances which activate the indigenous microbial agents involved in shipping fever

Two surveys recently made in large American hospitals highlight the importance of endogenous microbial diseases in man At the New York Hospital 54 per cent of the fatal infections observed in 1957 58 occurred while the patients were under care on the medical wards most of the infections were caused by microbes of low virulence and were brought about by therapeutic procedures directed at other disease conditions (Rogers 1959) At the Mayo Clinic only half of the 294 cases of meningitis studied during the 1950s could be traced to the classic etiologic agents of this condition namely meningococci pneumococci or influenza bacilli the other cases were caused by common organisms such as *E coli Pseudomonas* coagulase negative staphylococci etc not usually regarded as virulent

MICROBIAL PERSISTERS

The fact that most pathogens—viruses rickettsia fungi bacteria protozoa and even helminths—can persist in the body in a non active state for prolonged periods of time

and that many types of microbes are always present in the tissues of all normal individuals is at the origin of some of the most important and most perplexing problems of epidemiology and clinical medicine Furthermore it has given rise to an extensive and rather confusing terminology The expressions carrier state latent inapparent or dormant infection masking and unmasking of viruses etc have never been clearly defined and it is often difficult to differentiate the shades of meaning which they are supposed to convey More recently the word persister has been introduced to designate the parasites which survive in tissues despite successful and prolonged chemotherapy (McDermott 1958 1959)

It will suffice to point out here that pathogens and other microbes can persist in the body in a number of different states At one extreme are those situations in which the pathogen exists in the tissues in a form which can be demonstrated readily by standard technical procedures The recovery of typhoid bacilli from typhoid carriers or of the virus of herpes simplex from the tissues of normal persons are examples in point At the other extreme are the situations in which recovery of the pathogen is all but impossible as long as the latent infection has not evolved into an active pathologic process in the infected animal or person For example the epidemic strain of typhus (*Rickettsia prowazeki*) can persist in man for many decades and remain undetected until it causes the Brill Zinsser disease or again murine corynebacteria can persist in an undetectable form in rodents yet multiply explosively as a result of stress nutritional deficiencies or treatment with massive doses of cortisone (Fauve *et al* 1964)

Technical difficulties often account for the failure to isolate the pathogen Indeed it is only in specialized cases that the methods in use at present permit detection of a single or a few infective units Therefore the report that a pathogen is inapparent or masked must always be judged in terms of the sensitiveness of the procedure used to test for its presence In many cases infected tissues contain growth inhibitory substances which although not capable of destroying the pathogen which is being looked for in vivo nevertheless can inhibit its multiplication in vitro For example neutralizing antibody transferred from infected tissue along with a virus is likely to prevent the latter from becoming established in a recipient animal Tissue inhibitors other than antibodies can also cause difficulties as when tissue constituents prevent the growth of tubercle bacilli in otherwise favorable culture media Elimination of neutralizing antibodies and of other inhibitory agents is therefore a prerequisite for the successful demonstration of the presence of small numbers of infective units in the tissues but few if any are the cases in which this can be done adequately

Even more subtle mechanisms may be involved in the failure to recover pathogens from infected tissues Viruses can persist in vivo in the form of naked nucleic acid structures and bacteria in the form of protoplasts as long as they are sheltered in the well balanced environment of their hosts However such delicate infective structures are readily destroyed or inactivated when removed from their protective environment and as a result they usually escape detection by the customary laboratory procedures The role of such naked infective particles in disease has not yet been fully documented but their very existence illustrates nevertheless that many different mechanisms can account for the well established fact that microbes often persist in the tissues even when it is impossible to demonstrate their presence by ordinary microscopic or cultural technics Finally microbes can persist in a form which though readily culturable is so atypical as to prevent recognition For example the agent of murine corynebacterial pseudotuberculosis persists in vivo as an avirulent variant which reacquires virulence and multiplies extensively when the rodent is treated with cortisone (Fauve *et al* 1964)

Oddly enough the phenomenon of persistence has become more obvious and perhaps of greater practical importance as a result of the widespread use of chemotherapeutic agents Whereas antimicrobial drugs are often highly successful in arresting the progress of disease they rarely succeed in eradicating the causative agent from the tissues For example even after successful

treatment of scrub fever with tetracycline of gonorrhea with penicillin or of tuberculosis with isoniazid and other antimycobacterial drugs some of the causative rickettsia gonococci or tubercle bacilli persist in the tissues (McDermott 1958 1959 Smadel 1963) And so it is with many other types of infectious agents even following treatment with highly effective drugs

It is important to emphasize that contrary to common belief persisters are not necessarily forms of the organisms which have become genetically resistant to the drug used for therapy More often than not they are still drug susceptible in the genetic sense *but either they exist in a physiologically* resting form on which the drug is not active or they are located in parts of the body or in tissue cells which provide a protective shelter for them (McDermott 1958, 1959)

The production of persisters is not a phenomenon peculiar to chemotherapy It occurs also in the presence of protective antibodies because immunologic processes are rarely if ever more successful than antimicrobial drugs in fulfilling Paul Ehrlich s ideal of absolute sterilization In other words viruses bacteria and other pathogens can persist in the tissues even when the level of specific immunity *is high enough* to prevent the infection from progressing

THE PHENOMENON OF INFECTION IMMUNITY (PREMUNITION)

It has long been recognized that the persistence in the body of a given microbial agent is accompanied by a high level of resistance to superinfection with this same agent Such a state of resistance was early recognized and designated as infection immunity or premunition Although emphasized chiefly for its relevance to malaria tuberculosis syphilis and relapsing fever infection immunity is certainly of very general occurrence but its study has been grossly neglected New observations made during recent years should renew and stimulate scientific interest in this unorthodox yet highly interesting field of theoretical and practical immunology

An illuminating example of infection immunity has been provided recently by the study of the comparative resistance of several strains of mice to corynebacterial pseudo tuberculosis Mice of the C57 Black strain are highly resistant to the causative agent of this disease *Corynebacterium kutscheri* whereas mice of the albino Swiss strain are highly susceptible Cross mating between the 2 mouse strains gives results suggesting that their difference in susceptibility has a genetic basis However when normal C57 Black mice are treated with large doses of cortisone they succumb from spontaneous endogenous infection with *Corynebacterium kutscheri* a fact which proves that they normally harbor this organism In contrast, albino Swiss mice subjected to the same treatment do not develop the endogenous disease and therefore must not be carriers This correlation between carrier state and resistance to superinfection has been established for many other strains of mice In other words resistance to superinfection with the corynebacterium is in some manner correlated with the presence of persisters of this bacterial species (Fauve *et al* 1964)

These findings bring to mind the response of experimental animals to certain viral infections For example the virus of lymphocytic choriomeningitis produced a severe disease with *fatal outcome* when it was first introduced among albino mice but eventually it became established in several mouse colonies Within a few years after its introduction it was found to be present in all animals of these colonies producing in them a latent infection The infection was contracted in utero but did not manifest itself by any detectable sign of disease in adult animals even though their organs continued to harbor active virus throughout life In this case therefore a few years sufficed to change the type of relationship between mice and choriomeningitis virus from that of a virulent epidemic to a state of silent commensalism or symbiosis In many colonies the virus has become an unobtrusive guest the presence of which is barely noticed by the host but its presence renders the carrier mice resistant to superinfection

The response of animals to the polyoma virus provides another striking illustration of the resistance afforded by contact early in life with an infectious agent Injection of

the virus into a variety of species of experimental animals is likely to result in the production of many different kinds of tumors However it seems that this happens only if the animals used are obtained from a colony free of polyoma In contrast there is no evidence of tumor production in wild or laboratory populations of animals which normally carry the virus Therefore as in the case of corynebacteria the acquisition of a viral agent either in utero or very early in life may fail to produce any sign of disease yet profoundly alter the response of the host that harbors it to subsequent infection with this virus (Huebner 1961)

The findings just outlined point to the paradoxical conclusion that animals and probably human beings may behave as if they were genetically resistant to a given agent yet owe this behavior in reality to some modification of their tissue response brought about by the fact that they carry persister forms of this very agent Such infection immunity or premunition may also play some part in the life long immunity to viral infections which follows early exposure to the pathogen or vaccination with attenuated living vaccines

It is certain that the conditioning of response brought about by infection in utero or very early in life operates through several unrelated processes ranging from immune tolerance through cellular and humoral immunity to nonspecific stimulation of defense processes However whatever the theoretical basis of their individual mechanisms the various forms of infection immunity have in common certain practical consequences which suggest possible approaches to the control of some problems of infection It has been observed for example that human beings who carry *Escherichia coli* do not readily become superinfected with other strains of this bacterial species Furthermore recent clinical studies reveal that the colonization of human infants with virulent staphylococci can be prevented or retarded by early contamination nasal or umbilical with very small inocula of a coagulase positive strain of staphylococcus (selected because of its great susceptibility to penicillin and low virulence) Not only does the attenuated strain become lastingly established in the artificially contaminated infants it also spreads to other human contacts and the over all effect is to limit the dissemination of more virulent staphylococci (Shinefield *et al* 1963 Dubos 1963)

Thus it is apparent that the ubiquitous presence of a potential pathogen in a community can confer a high level of resistance to this particular agent Infection immunity probably does not constitute an immunologic entity but through the various mechanisms which permit microbial persistence it may play a very important role in the phenomenon of herd immunity

GENETIC DETERMINANTS OF MICROBIAL DISEASE

The changes which have occurred during historical times in the relation between man and the various microbial agents of disease suggest that either the latter undergo fluctuations in their infectivity and pathogenicity or that the resistance of man can fluctuate It is probable in fact that both mechanisms can operate—in certain cases singly and in others jointly

Of course viruses bacteria and other parasitic agents can undergo mutations affecting most of their characteristics including their immunologic specificity and their virulence While it is legitimate to assume that such mutations occur in nature so far it has not been possible to demonstrate convincingly that they play an important role in modifying the course of human epidemics However observations made with the virus of rabbit myxomatosis in Australia and Europe have established that genetic changes in virulence can occur under natural epidemic conditions

The European rabbit was introduced in Australia in 1859 As it had no natural enemies in its new habitat it spread rapidly over much of the continent and multiplied enormously The rabbit population eventually reached several billions thus creating a grave threat for the agricultural economy of Australia In 1950 the virus of myxomatosis was introduced in an attempt to control the rabbit population Myxomatosis occurs naturally in the wild rabbits of Brazil but merely in the form of a benign tumor asso

ciated with only a mild and transient viremia The relationship between the Brazilian rabbit and the myxoma virus clearly denotes an ancient association resulting in ecologic equilibrium In contrast European rabbits which had never had any contact with the virus uniformly develop an acute almost always fatal disease when inoculated even with very small doses

The initial outbreaks of myxomatosis immediately after introduction of the virus in Australia were characterized by an enormously high case mortality rate—higher than 99 per cent Within a short time however the case mortality had fallen to 90 per cent in areas where a second spontaneous outbreak had occurred Interestingly enough it turned out that this lower mortality was due in part to a decrease in the virulence of the virus Some details concerning this phenomenon are of interest here because the decrease in virulence was unexpected and probably has general significance for epidemiologic theory

In Australia the virus is transmitted from rabbit to rabbit almost entirely through mosquitoes which act mechanically as flying needles Because the highly virulent strains of virus kill rabbits within a very few days the chance for their transmission through the mosquito vector is rather limited However when attenuated mutant strains of the virus appeared spontaneously they produced a less rapidly fatal disease and the rabbit developed skin lesions of longer duration Thus the less virulent mutant strains had a better chance of being transmitted through mosquito bites and they progressively displaced the original highly virulent strain in the field A few years after the introduction of myxomatosis in Australia viral strains recovered from the field caused a mortality of 90 per cent in laboratory rabbits instead of 99 per cent as had been the case with the strain originally introduced (Fenner 1959)

While the evolution of rabbit myxomatosis in Australia can be explained in part by hereditary changes in the virus there is no doubt that it has been influenced also by hereditary changes in the host As already mentioned the European type of rabbit introduced in Australia is immensely susceptible to myxomatosis a disease with which it had no racial experience until a few years ago Now, however rabbits trapped in areas where the infection has been prevalent for several years exhibit a degree of resistance to the most virulent forms of the virus much higher than that exhibited by rabbits before the beginning of the epizootic or by rabbits carefully and constantly maintained in isolation This increase in resistance has a genetic basis and therefore must result from the selection of mutant animals which had survived the initial outbreak Genetic changes in resistance to infection are of course common among animals In fact it is possible almost at will to select and breed laboratory animals having a high resistance or high susceptibility to one or another type of bacterial or viral infections (Lurie 1941 Webster, 1946)

It seems reasonable to believe but difficult to prove that genetic changes also occur in the resistance of man to his pathogens Since epidemics with a great killing power among young people tend to eliminate a large percentage of those having a high degree of susceptibility the likely outcome is the selective survival of that segment of the population endowed with a higher than average innate resistance Thus genetic resistance progressively accumulates in the affected population The history of family groups strongly suggests that such a selective process resulting in higher herd resistance operated in Europe and America during the 19th century epidemic of tuberculosis as it certainly did when tuberculosis eliminated half the families among the Indians of the Qu Appelle Valley reservation (Ferguson 1955 Puffer 1944 Dubos and Dubos 1952) It is probable indeed that the decrease in the severity of tuberculosis in the countries of Western civilization during the past few decades has been brought about not only by improvements in standards of living and in medical care but also in no small part by genetic changes

There are indications that a similar genetic selection has taken place in the Orient with regard to leprosy Among people living today in the Hawaiian Islands the Chinese the Japanese and other Oriental people originating from areas where *Mycobacterium leprae* has long been ubiquitous seem to suffer from this disease far less commonly

than do the Polynesians who became exposed to it for the first time during recent centuries

A slight loss of virulence by the parasite and some increase in the genetic resistance of the host provide the right conditions for the development of acquired immunity in a large percentage of infected individuals Here again rabbit myxomatosis in Australia constitutes an enlightening model Protective antibodies have been found in the surviving animals trapped in infected areas Therefore it can be surmised that the transmission of maternal antibodies helps the young to withstand infection during the first days of life and thereby allows them to develop their own active immunity

The many interrelated aspects of this problem cannot be discussed here but it seems to be worth pointing out that the genetic and immunologic changes favoring resistance to infection which occur during a generalized epidemic are the almost inevitable outcome of prolonged contact between any parasite and any host For this reason it seems unlikely that living species can ever be completely wiped out by epidemics however virulent the parasite The outcome of evolutionary forces is of necessity a *modus vivendi* according to which the parasite and the host reach some sort of equilibrium which permits the survival of both The concept of successful parasitism so ably formulated by Theobald Smith (1934) and N H Swellengrebel (1940) a generation ago is another expression of this evolutionary equilibrium resulting from prolonged racial contact between host and parasite

Evolutionary adaptation between hosts and their parasites helps to explain why the ability or the failure of a particular microorganism to cause disease cannot be fully explained in terms of the concepts encompassed by the word virulence The need to redefine virulence in terms of host parasite relationships will now be illustrated by consideration of malignant malaria in primitive populations

Plasmodium falciparum possesses attributes which make it highly virulent for most members of the human race Yet this parasite produces only a rather mild disease in the Bush Negroes who live in the area included in former Dutch Guinea While over 90 per cent of these Negroes become infected with the malignant form of plasmodium shortly after birth the infection contributes little if anything to infant mortality among them Most adults if not all harbor the parasite in their blood but the intensity of parasitemia decreases with advancing age

The extent of splenomegaly constitutes further evidence of the mildness of malaria in Bush Negroes Among them the spleen rate declines from a high of over 80 per cent in infants to less than 15 per cent in adults The fact that such a large percentage of adults show parasitemia without splenomegaly illustrates the two complementary determinants of the infectious process On the one hand the parasite is virulent since it can become established multiply and persist in the tissues On the other hand the Bush Negro is resistant to the parasite since he can keep its proliferation under control and since his response to its presence is so mild that the infection usually fails to express itself in overt clinical disease (Swellengrebel 1940)

The probable explanation of these findings is that the Bush Negroes of Dutch Guinea have evolved in constant contact with plasmodia Widespread infection constitutes a selective force favoring the kind of genetic endowment which makes it possible for human hosts and virulent parasites to coexist in a state of biologic equilibrium In the case of African Negroes as is well known possession of the sickle cell gene constitutes one of the attributes of resistance to malaria Needless to say immune responses reinforce the effectiveness of genetic mechanisms when the parasite is ubiquitous in the environment

Similar phenomena of adaptive host parasite relationships certainly occur in all other infectious diseases of mankind On a few occasions during historical times the social and economic circumstances proved to be favorable for the spread of *Pasteurella pestis* among the population of Western Europe and every time the mortality that it caused was enormous During the Justinian era in the Roman world and again during the Renaissance in Italy France England and other parts of Europe whole areas were decimated by the bubonic and pneumonic

forms of plague *Pasteurella pestis* is still widely distributed today in certain parts of Asia but granted that it constitutes an important cause of disease in these populations it does not behave toward them as the terrible scourge which almost depopulated Europe on two occasions Similarly cholera can run a fulminating fatal course in people exposed for the first time to its causative vibrio yet the disease is commonly present as a rather mild annoyance in many bazaars of Asia

Like protozoa and bacteria viruses also tend to approach a state of biologic equilibrium with man Thus, a great variety of respiratory infections which are now extremely common and rather mild in our communities are caused by viruses which probably were at a time responsible for more severe pathologic processes Evolutionary adaptation may have taken place even in the case of paralytic poliomyelitis Until recent times most human beings in our communities became infected with polio viruses but only a very small percentage of the infected persons developed paralytic disease in general the infection expressed itself in the form of symptoms so mild as to be overlooked True enough maternal antibodies did account in large part for the failure to develop disease following infection but it is probable that genetic mechanisms of resistance were also involved

Herpes simplex infection is of special interest in this regard because the virus is potentially capable of causing acute and fatal encephalitis More generally however large numbers of children and young adults become infected without displaying severe pathologic signs and they continue to carry the virus throughout life In our communities herpes infection is known chiefly in the form of fever blisters a self limiting disease which occurs only when the carrier of the virus is under some form of physiologic stress Man has come close to achieving a state of biologic adaptation to the herpes virus as well as to many other viruses which are ubiquitous in his communities

THE ACTIVATION OF ENDOGENOUS MICROBIAL DISEASE

In the late stages of evolutionary adaptation between a given parasite and its host in a given community infection is extremely prevalent but it rarely evolves into overt and fatal disease Thus, given enough time a state of peaceful coexistence can be established between any host and any parasite Microbial persistence not accompanied by acute or destructive pathologic processes is therefore not a laboratory freak not a rare phenomenon engendered by tricky manipulations of antimicrobial drugs or immunologic responses Throughout nature, infection without disease is the rule rather than the exception

However latent infections can become activated by many different kinds of changes either in the host or in the environment For this reason a large and most important aspect of the epidemiology of disease (as contrasted with the epidemiology of infection) has to do with the factors which upset the equilibrium between host and parasite and thereby convert dormant infection into overt disease

Maintenance of health despite persisting infection means of course that the mechanisms of physiologic resistance and the humoral or cellular processes involved in acquired immunity are capable of inhibiting the multiplication of the parasites but not of eradicating them from the tissues However this does not imply that acquired immunity necessarily results in freedom from disease for there are many types of physiologic disturbances which allow the parasite to multiply extensively even if the host is specifically immune to it For example persons who carry the virus of herpes simplex commonly have a high level of neutralizing antibodies for this virus in their serum nevertheless they can experience transient episodes of viral multiplication under the influence of nonspecific stimuli—such as certain types of fever excessive exposure to the sun fatigue menstruation or section of the trigeminal nerve The result is then the production of herpes blisters even in the presence of humoral immunity to the virus

On the basis of clinical experience as well as of common observation it is usually considered to be self evident that susceptibility to all sorts of infectious agents is much increased by the various stresses and strains of life Patients as well as their physicians tend to incriminate poor constitution bad

weather lack of sleep or emotional disturbances in the causation of disease even when it is certain that the signs and symptoms result from the activities of viruses or bacteria The life situations which have been assumed to be responsible for the activation of endogenous microbial disease range all the way from the physiologic misery and d privations of internees in concentration camps to the emotional upsets resulting from business failure or an unhappy love affair

Unfortunately few are the cases in which a convincing correlation has been established between the physiologic state of the host and his susceptibility to infection Diabetes constitutes probably the best-documented example of this type of relationship since there is no doubt that the poorly controlled diabetic patient is easy prey to staphylococci tubercle bacilli and many other kinds of bacteria It is also true on the other hand that his resistance to infection becomes almost normal once the diabetes is controlled by adequate insulin therapy In this case therefore the response of the host to infection is under the influence of events perhaps biochemical in nature which can be altered reversibly by the physiologic control mediated through insulin Certain therapeutic procedures also can increase susceptibility to infection As already mentioned the very use of antibacterial drugs not uncommonly favors the multiplication in vivo of microorganisms which are not susceptible to these drugs probably by first eliminating the normal body flora Extensive surgery and any form of trauma especially if it results in a state of shock is another procedure which can render partially ineffective the defense mechanisms of the body at least for a while

Therefore it is certain that many nonspecific stresses increase the vulnerability of the host, but there is little if any understanding of the mechanisms through which these effects are exerted Indeed many of the relationships that are believed to be so obvious as to need no demonstration in reality have proved to be almost impossible to reproduce in the laboratory For example it is often difficult to increase the susceptibility of animals to infection by nutritional deficiencies temperature changes or emotional upsets More surprisingly experiments in human volunteers fail in many cases to provide clear evidence that exposure to cold and other forms of bad weather increases susceptibility to upper respiratory infections Because of these difficulties it has not yet been feasible to identify the physiologic and biochemical mechanisms through which environmental stresses alter the body response to microbial agents

A few forms of activation of endogenous disease have been consistently reproduced and studied in laboratory models Thus as already mentioned the susceptibility of experimental animals to infections caused by the microbial agents that they normally carry in their tissues can be consistently increased by administration of antibacterial drugs by production of traumatic shock or by extensive body irradiation Treatment with large doses of cortisone is one of the most popular laboratory technics of activation a fact of great importance since administration of this hormone has been a frequent cause of grave clinical accidents in man The infection enhancing effect of cortisone may provide a clue for the analysis of a large and ill understood problem namely the manner in which environmental stimuli including emotional disturbances affect endocrine activity and thereby modify indirectly resistance to disease ACTH also can enhance infection in certain experimental models and its enhancing effect can be neutralized by the proper dose of somatotrophic hormone Injection of thyroid hormone into rabbits markedly increases their resistance to experimental tuberculosis but in contrast hypothyroidism seems to be associated with increased susceptibility to other infections

While it is certain that the course of infectious processes can be altered profoundly by a variety of hormonal influences the mechanisms involved are far from clear The fact that cortisone interferes with the production of antibodies under certain conditions seems at first sight to provide the clue to the problem but this immunologic inhibition cannot account entirely for the infection enhancing effect of the hormone In addition to interfering with antibody production cortisone influences many other physiologic processes some of which may affect directly or indirectly the response of the body to infection Interference with the inflammatory response and with the activity of the reticulo

forms of plague *Pasteurella pestis* is still widely distributed today in certain parts of Asia but granted that it constitutes an important cause of disease in these populations it does not behave toward them as the terrible scourge which almost depopulated Europe on two occasions Similarly cholera can run a fulminating fatal course in people exposed for the first time to its causative vibrio yet the disease is commonly present as a rather mild annoyance in many bazaars of Asia

Like protozoa and bacteria viruses also tend to approach a state of biologic equilibrium with man Thus a great variety of respiratory infections which are now extremely common and rather mild in our communities are caused by viruses which probably were at a time responsible for more severe pathologic processes Evolutionary adaptation may have taken place even in the case of paralytic poliomyelitis Until recent times most human beings in our communities became infected with polio viruses but only a very small percentage of the infected persons developed paralytic disease in general the infection expressed itself in the form of symptoms so mild as to be overlooked True enough maternal antibodies did account in large part for the failure to develop disease following infection but it is probable that genetic mechanisms of resistance were also involved

Herpes simplex infection is of special interest in this regard because the virus is potentially capable of causing acute and fatal encephalitis More generally however large numbers of children and young adults become infected without displaying severe pathologic signs and they continue to carry the virus throughout life In our communities herpes infection is known chiefly in the form of fever blisters a self limiting disease which occurs only when the carrier of the virus is under some form of physiologic stress Man has come close to achieving a state of biologic adaptation to the herpes virus as well as to many other viruses which are ubiquitous in his communities

THE ACTIVATION OF ENDOGENOUS MICROBIAL DISEASE

In the late stages of evolutionary adaptation between a given parasite and its host in a given community infection is extremely prevalent but it rarely evolves into overt and fatal disease Thus given enough time a state of peaceful coexistence can be established between any host and any parasite Microbial persistence not accompanied by acute or destructive pathologic processes is *therefore not a laboratory freak* not a rare phenomenon engendered by tricky manipulations of antimicrobial drugs or immunologic responses Throughout nature infection without disease is the rule rather than the exception

However latent infections can become activated by many different kinds of changes either in the host or in the environment For this reason a large and most important aspect of the epidemiology of disease (as contrasted with the epidemiology of infection) has to do with the factors which upset the equilibrium between host and parasite and thereby convert dormant infection into overt disease

Maintenance of health despite persisting *infection means of course that the mecha*nisms of physiologic resistance and the humoral or cellular processes involved in acquired immunity are capable of inhibiting the multiplication of the parasites but not of eradicating them from the tissues However this does not imply that acquired immunity necessarily results in freedom from disease for there are many types of physiologic disturbances which allow the parasite to multiply extensively even if the host is specifically immune to it For example persons who carry the virus of herpes simplex commonly *have a high level of neutralizing antibodies* for this virus in their serum nevertheless they can experience transient episodes of viral multiplication under the influence of nonspecific stimuli—such as certain types of fever excessive exposure to the sun fatigue menstruation or section of the trigeminal nerve The result is then the production of herpes blisters even in the presence of humoral immunity to the virus

On the basis of clinical experience as well as of common observation it is usually considered to be self evident that susceptibility to all sorts of infectious agents is much increased by the various stresses and strains of life Patients as well as their physicians tend to incriminate poor constitution bad

of microbial diseases leaves no doubt furthermore that changes can occur in the parasite in the host and in the type of relationship that exists between them That the changes can occur rapidly has been shown with myxomatosis in rabbits and also with lymphocytic choriomeningitis in mice

It is clear in conclusion that the type of relationship existing at any given time between hosts and their parasites is the outcome of many different factors including past racial experience evolutionary adaptation through genetic changes and immunologic processes transient disturbances in the internal and the external environments In the classic infections of exogenous origin the determining etiologic event of the disease is exposure to the infective microorganism In endogenous microbial disease the immediate cause is the *environmental factor* which upsets the biologic equilibrium that normally exists between the host and the microbial agents (persisters) This profound difference in etiologic mechanism suggests that the methods used in the control of microbial diseases both prophylactically and therapeutically must differ from place to place and vary from time to time The methods of sanitation and vaccination that were designed to cope with the great epidemics of the past will not prove to be effective in the control of the disease states caused by microbial agents which are ubiquitous in our communities in the form of dormant infections

So far the main goal of medical microbiology has been to prevent infection from taking place or if it occurs to treat disease once it has become established The technics designed to this end aim at attacking the microbial agents It might be worth considering now whether useful practices of disease control can be derived from the fact that peaceful coexistence with pathogens often occurs in nature This approach will require that the determinants of infection be separated conceptually from the determinants of disease its objective will be to understand and control the processes which are responsible for converting infection into overt disease

endothelial system disturbance of intermediary metabolism activation of proteolytic enzymes are only a few of the effects of cortisone that might be of importance in this regard

Nutrition is one of the environmental factors for which it is easy to postulate hypothetical mechanisms explaining a role in infectious processes Once pathogens have become established in the body, there come into play a variety of responses that tend to limit their spread beyond the site of the initial lesion One of the essential components of the walling off process is the deposition of fibrin of the sulfated polysaccharides of reticulum and finally of collagen The very nature of this response involving as it does the synthesis of large amounts of special polysaccharides and proteins points to the possibility that it can be interfered with by many metabolic and nutritional disturbances For example deficiency in vitamin C or in dietary sulfur is known to retard the production of reticulum similarly quantitative or qualitative inadequacies in intake of protein or amino acids can handicap the production of fibrin and collagen It has been shown in fact that the rate of healing of wounds is influenced markedly by these dietary factors

There is no doubt that nutritional deficiencies play a decisive role in the prevalence and the severity of microbial diseases among underprivileged people For example the very high susceptibility of patients suffering from kwashiorkor to all sorts of viral bacterial and parasitic diseases is a direct consequence of protein malnutrition However in our own communities it is far more difficult to relate microbial diseases to the nutritional state The problem is further complicated by the fact that paradoxically enough certain nutritional deficiencies seem to increase rather than decrease the resistance to certain viral infections (Reviewed in Dubos and Schaedler 1959, Scrimshaw *et al* 1959)

DETERMINANTS OF MICROBIAL DISEASE

Thus many are the ways in which the total environment can affect the interplay between man and the countless microbial agents which he normally carries or with which he comes into contact This interplay can result in disease or be compatible with the maintenance of health, depending on the environmental circumstances under which the encounter between man and microbe takes place In other words the ecology of microbial disease is under the influence of factors both general and local independent of those which control the frequency of contact with infectious agents To a large extent endogenous microbial diseases are therefore indirectly the expressions of environmental forces

The relative importance of the factors which determine the chance that infection will take place and of those responsible for converting latent infection into overt disease is conditioned naturally by the characteristics of each particular microbial agent but also varies from one population and one community to another When a group of people whatever the race first comes into contact with a pathogen the chance is great that the general mechanisms of resistance will be of little avail and that infection will become manifest in the form of severe disease in a very large percentage of the persons infected This type of situation developed when smallpox measles tuberculosis etc were first introduced among the Amerindians and other primitive people It was produced experimentally by introducing the myxoma virus among the rabbits in Australia and Europe It probably would happen again if yellow fever plague or any type of infections with which Western man has not had wide contact recently were introduced for the purpose of biologic warfare The possibility that mutants of common pathogens can behave as new agents of disease against which the general mechanisms of resistance is of little avail has been suggested to account for the virulence of widespread epidemics like the influenza of 1918 1919

At the other extreme are the epidemiologic situations in which a particular microorganism is ubiquitous in a given community and becomes established in a latent form as a persister in most normal individuals Since the event of infection is not the variable in this type of epidemiologic system the factors that upset the ecologic equilibrium between host and parasite then become the effective determinants of disease Needless to say there are many intermediate situations between these two extremes and the evolution

of microbial diseases leaves no doubt furthermore that changes can occur in the parasite in the host and in the type of relationship that exists between them That the changes can occur rapidly has been shown with myxomatosis in rabbits and also with lymphocytic choriomeningitis in mice

It is clear in conclusion that the type of relationship existing at any given time between hosts and their parasites is the outcome of many different factors including past racial experience evolutionary adaptation through genetic changes and immunologic processes transient disturbances in the internal and the external environments In the classic infections of exogenous origin the determining etiologic event of the disease is exposure to the infective microorganism In endogenous microbial disease the immediate cause is the environmental factor which upsets the biologic equilibrium that normally exists between the host and the microbial agents (persisters) This profound difference in etiologic mechanism suggests that the methods used in the control of microbial diseases both prophylactically and therapeutically must differ from place to place and vary from time to time The methods of sanitation and vaccination that were designed to cope with the great epidemics of the past will not prove to be effective in the control of the disease states caused by microbial agents which are ubiquitous in our communities in the form of dormant infections

So far the main goal of medical microbiology has been to prevent infection from taking place or if it occurs to treat disease once it has become established The technics designed to this end aim at attacking the microbial agents It might be worth considering now whether useful practices of disease control can be derived from the fact that peaceful coexistence with pathogens often occurs in nature This approach will require that the determinants of infection be separated conceptually from the determinants of disease its objective will be to understand and control the processes which are responsible for converting infection into overt disease

Morphology and Chemical Anatomy of Bacteria*

METHODS

Before 1940 practically all investigations on the morphology and the structure of bacterial cells were performed by ordinary light microscopy using bright or darkfield illumination During the last 20 years several new methods of microscopy have been developed Thus the technics for phase contrast anoptral (Wilska 1954) and fluorescence (Nairn 1962) light microscopy and electron microscopy (Kay 1962) have come into use in bacteriologic research

Under the ordinary microscope living unstained bacteria appear without much contrast against the surrounding medium (Fig 1 A) To enhance the contrast the bacteria may be stained (Fig 1 D) It is also possible to stain selectively certain structures within the bacterial cells (Fig 1 E Fig 2 Fig 28) Before the cells are stained usually they are fixed by heat or chemical agents vital stains are seldom used in bacteriology It is well to remember that fixation and staining procedures may produce artifacts (Murray 1960) Thus structural details appearing in stained preparations should be interpreted with caution

Under the phase contrast and anoptral microscope living bacteria appear with considerable contrast against the background and internal structures may become visible (Fig 1 B) The halo seen around bacteria in the phase contrast microscope is not noticeable when the anoptral microscope is used Dark field illumination especially brightens intracellular inclusions and the outlines of the organisms (Fig 1 C) Structural elements of bacterial cells may also be detected by means of fluorescence microscopy (Fig 1 F)

The resolving power of a light microscope is at best about 0 2 μ when visible light is used for illumination of the object Since most bacteria have a width of only 0 5 to 1 μ the light microscope is not well suited for investigations of structural details of bacterial cells For such studies the electron microscope may be used The resolving power of the electron microscope extends to approximately 1 mμ, i e more than a 100 fold better than that of the light microscope However with the exception of some preliminary experiments (Dupouy Perrier and Durrieu 1960) only fixed specimens have been studied under the electron microscope Thus artifacts may appear in electron micrographs of bacteria as in stained bacterial specimens designed for light microscopy

Electron micrographs of whole untreated bacteria reveal little beyond their size and shape (Fig 8) To obtain information on bacterial subcellular structures the specimens must be sectioned (Figs 15 to 19 24)

Staining methods especially the negative staining technic has also proved to be useful (Fig 26)

Chemical and physicochemical methods have become increasingly important for investigations on the structure of the bacterial cell The term chemical anatomy is an expression for this trend in bacteriologic research The first step of such an investigation often consists of fragmentation of the cells by mechanical or enzymatic means The homogenate thus obtained is subjected to a differential centrifugation to obtain a certain cell component in a purified state (Figs 7 22) The isolated component is studied subsequently by chemical or physicochemical methods

FIG 2 *Corynebacterium diphtheriae* with stained metachromatic granules (× 3 000)

To localize certain chemical compounds in bacterial cells high resolution radioautography may be used (Fig 30) Bacterial enzymes have also been localized by bombarding parts of the cells with low voltage electrons (Preiss and Pollard 1961)

SHAPE SPATIAL ARRANGEMENT AND SIZE OF BACTERIAL CELLS

The discoverer of the bacteria Leeuwenhoek observed that these organisms occur in 3 main forms the spherical the rodlike (cylindrical) and the spiral (helical) Spherical or approximately spherical bacteria (Fig 3 *top* and *bottom left*) are named cocci rodlike ones (Fig 1) bacilli and helical ones spirilla (Fig 3 *bottom right*) or spirochaetes (Fig 4 *top*) Within these main types several subtypes may be discerned Rodlike bacteria are sometimes very short and then may be called coccobacilli Bacilli tapering at both ends are named fusiform Very long bacteria (Fig 5 *left*) are often considered as filamentous rather than rodlike Filamentous bacteria may be branched (Fig 4 *bottom*) Spiral bacteria may form either rigid helices (spirilla) or flexible ones (spirochaetes)

Some bacteria cannot be fitted into any of the main morphologic types mentioned above as for example the stalked bacteria (Houwink 1955 Fig 6) In old bacterial cultures containing a high percentage of dead or devitalized cells irregularly shaped organisms so called involution forms may be seen (Fig 5 *right*)

Most bacteria multiply by binary fission If the 2 cells formed by the fission process separate from each other immediately after they are formed a population of single bacterial cells results Often however the bacterial cells remain attached to one another on one or several subsequent divisions Thus the bacteria may occur in pairs (diplococci or diplobacilli Fig 3 *top left*) or form multicellular aggregates Depending on the mode of division several types of aggregates may result If the multiplication occurs in one plane chains of cells are formed (strepto

FIG 5 A *Mycoplasma* sp (× 2 400 phase contrast) (*Left*) Twelve hour cells (*Right*) One hundred hour cells (Weibull and Lundin 1963)

cocci or streptobacilli Fig 3 *top right*) If cocci multiply in 2 planes at right angles to one another squares of 4 cells may appear (tetrads tetracocci) Cubical packets of cells (sarcinae) may result if the division takes place in 3 planes at right angles to one another Some cocci (staphylococci) divide in several planes at indefinite angles to one another thus forming irregular clusters of cells (Fig 3 *bottom left*) Septa of bacterial cell wall material may not be visible under the light microscope Thus what appears as a single bacillus may consist in fact of several complete cells (Fig 1 F G and H)

Most bacteria especially those of medical interest have dimensions around 1 μ The width (diameter) of bacterial cells ranges from 0 2 or 0 3 μ (the *Mycoplasmatales*) to 3 μ or more (*Caryophanon*) Some spirilla have a length of 20 to 50 μ and filamentous bacteria and free living spirochaetes may be more than 100 μ long

The order of *Eubacteriales* represents the group of bacteria that has been studied most thoroughly from the standpoint of cellular structure However investigations performed on members of other orders e g the *Actinomycetales* (Glauert 1962 Imaeda and Convit 1962) the *Myxobacterales* (Mason and Powelson 1958 Voelz and Dworkin 1962) and the *Mycoplasmatales* (Klieneberger-Nobel 1962) suggest that the main features of cellular anatomy are similar in most sub groups of the class of *Schizomycetes*

FLAGELLA AND FIMBRIAE

MORPHOLOGY AND ARRANGEMENT OF THE FLAGELLA

The flagella form filamentous appendages to the bacterial cells They are between 100 and 200 A thick and usually have a helical shape (Figs 7 to 10) Normally the wave length of the helices is relatively constant within a species or strain Sometimes however a phenomenon called biplicity occurs i e 2 distinct wavelengths are observed one approximately twice the length of the other (Fig 9) Additional variations in flagellar morphology have been described by Leifson (1960 1961)

On account of their thinness individual flagella on living bacteria cannot be observed in the light microscope with ordinary or phase contrast illumination However the flagella have a strong tendency toward aggregation The bundles thus formed may be seen in the phase contrast microscope and still better with darkfield illumination (Fig 10)

Frequently, staining methods have been used for the study of bacterial flagella (Leifson 1960) The diameter of flagella may be grossly enlarged by such procedures On the other hand the staining may not affect the

wave shape of the flagella to any great degree

Two main types of arrangement of the flagella on bacterial cells may be discerned polar and peritrichous flagellation In the former case the flagella originate from one or both ends of the cells (Fig 8 *top right*) in the latter they are distributed at random on the cell surface (Fig 8 *top left*) Generally the flagellated *Pseudomonadales* belong to the former type the flagellated *Eubacteriales* to the latter The various types of flagellation have been discussed in detail by Leifson (1960)

It was thought for some time that the spirochaetes possess flagella However the flagellar structure described by some workers evidently represent detached filaments which are wound tightly around the cell body of living spirochaetes (van Iterson 1956 Weibull 1960 Kawata 1961 Fig 8 *bottom*)

The cytoplasmic origin of flagella is established by the fact that they remain attached to the bacterial protoplast after the wall has been dissolved by lysozyme (Weibull 1960) Several electron micrographs especially of lysed bacteria (Weibull 1960 Fig 8 *top right*) suggest that the flagella are attached to basal granules like flagella of higher organisms

Fig 6 *Caulobacter* sp attached to *Bacillus megaterium* (× 3 500 orig × 6 000) Electron micrograph from Houwink (1955)

Structure and Chemical Composition of Flagella

Chemical investigations on flagella isolated from *Proteus Bacillus Serratia* and *Salmonella* spp (Ambler and Rees 1959 Kobayashi Rinker and Koffler 1959 Weibull 1960) indicate that these organelles consist exclusively of proteinaceous material Only traces of lipids carbohydrates and nucleic acids were found in carefully purified flagella preparations The flagellar proteins which have been named flagellins generally seem to lack the amino acids tryptophan and proline

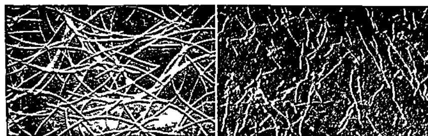

Fig 7 Purified cell components of *Proteus vulgaris* (× 30 000) (*Left*) Flagella (*Right*) Fimbriae Electron microscopy (Weibull and Hedvall 1953)

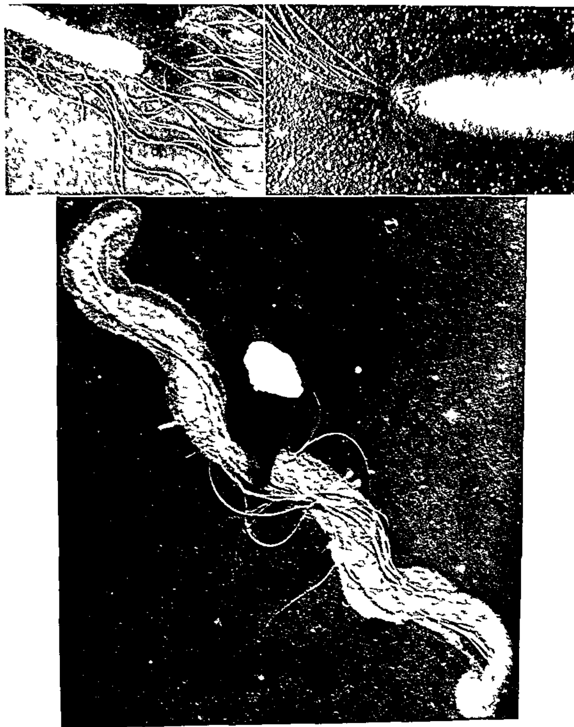

FIG 8 Electron micrographs of unsectioned bacteria (*Top left*) Peritrichously flagellated *Proteus vulgaris* (× 10 000) (Weibull C Biochim Biophys Acta *2* 351 1948) (*Top right*) Polarly flagellated *Spirillum lunatum* with basal granules (× 24 000 orig × 48 000) (Williams M A and Chapman G B J Bact *81* 195 1961) (*Bottom*) A spirochete with filaments wound around the cell (× 22 000) (van Iterson 1956)

X ray investigations have revealed that the bacterial flagella belong to the keratin myosin-epidermin fibrinogen type of fibrous proteins (Beighton Porter and Stocker 1958, Weibull 1960 Burge 1961) Physicochemical studies have shown that the flagella consist of subunits having a molecular weight of approximately 20 000 (Erlander Koffler and Foster 1960) Electron micrographs of sectioned flagella (Kerridge Horne and Glauert 1962) indicate that they do not contain the 9 peripheral and the 2 central subfibrils that are characteristic for flagella of higher organisms rather they appear to consist in some cases of spirally wound subfibrils (Weibull 1960 Marx and Heumann 1962) or of spherical subunits (Kerridge Horne and Glauert 1962)

Function of the Flagella

Most students of bacterial motility have been of the opinion that the flagella are motor organs However some workers advocate the view that the flagella are merely passive appendages of the bacterial cell (Pijper 1957 1962 Winkler and Tscheuschner 1958) The best support to the former view has been given by Stocker and Campbell (1959) who showed that nonlethal treatment which removes the flagella from bacterial cells is associated with loss of motility Motility is resumed when the flagella are resynthesized Hydrodynamic calculations (Weibull 1960 Holwill and Burge 1963) also favor the view that the flagella are motor organs The motility problem has been reviewed in detail by Pijper (1957) and Weibull (1960)

The bacterial H antigens are located in the flagella the proteinaceous nature of the flagella is in keeping with the heat lability of these antigens

Fimbriae

A second type of filamentous appendages of bacterial cells is represented by organelles named fimbriae (Duguid and Wilkinson 1961) or pili (Brinton 1959) They are thinner than flagella and are not curved in regular spirals or waves (Fig 7 *right* Fig 11) Fimbriae have been observed in *Aerobacter Escherichia Klebsiella Proteus Pseudomonas Salmonella* and *Shigella* spp

Fig 9 Cells of *Proteus morganii* stained with flagellar stain Note biplicity (× 1 800) (Leifson 1960)

(Weibull 1960 Duguid and Wilkinson 1961 Marx and Heumann 1962)

Not much is known about the structure and the chemistry of the fimbriae They may contain some proteinaceous material (Brinton 1959) but seem to be resistant to trypsin pepsin and to acid and alkaline environments (Weibull and Hedvall 1953)

The fimbriae do not seem to be related to motility since motile bacteria may be nonfimbriate and nonmotile bacteria may possess fimbriae On the other hand the fimbriae seem to be associated with the ability of bacterial cells to adhere to the surface of other bodies Thus most fimbriate bacteria possess hemagglutinating power whereas nonfimbriate strains are nonhemagglutinating (Brinton 1959 Duguid and Wilkinson 1961)

THE SURFACE LAYERS OF THE BACTERIAL CELL

The peripheral part of the cell may be divided into 3 layers (1) the capsule or

THE SURFACE LAYERS OF THE BACTERIAL CELL

The peripheral part of the cell may be divided into 3 layers (1) the capsule or

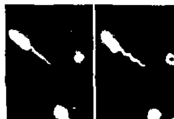

Fig 10 Flagellated cells of *Salmonella typhosa* (*left*) moving (*right*) motionless Sunlight darkfield (× 1 000) (Pijper A J Roy Micr Soc *81* 61 1962)

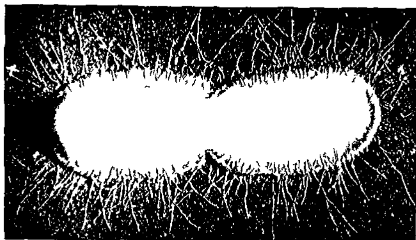

FIG 11 Fimbriate cell of *Shigella flexneri* (× 24 000) Electron micrograph from Duguid and Wilkinson (1961)

slime layer (2) the cell wall and (3) the cytoplasmic membrane The capsule which forms the outermost layer of the cell is difficult to define usually capsules are demonstrable by the light microscope and their removal from a bacterium does not cause the death of the organism The cell wall is commonly defined as the rigid structure which gives a bacterium its characteristic shape The cytoplasmic membrane is considered as a part of the bacterial cytoplasm It is flexible and semipermeable serving to regulate the osmotic pressure inside the cells

Physiologic chemical mechanical or morphologic criteria have been used by various workers to define the surface layers of bacteria Since results sometimes differ depending on the criterion it is difficult to decide with certainty to which of the surface layers certain structures or chemical compounds should be assigned

The streptococcal M proteins for example can be removed enzymatically from living bacteria without killing them (Salton 1953) On this basis the M proteins could be regarded as capsular substances However the removal of these compounds does not change the morphology of streptococcal cell walls (Salton 1953 Slade 1957) Using the terminology of Wilkinson (1958) the M proteins might therefore be considered as microcapsular substances At present no conclusion can be drawn as to the precise location of the M proteins

Many gram negative bacteria lose their O antigens by nonlethal mutations Thus the O antigens might be considered as microcapsular substances since bacteria possessing these substances as a rule do not possess capsules *demonstrable in the light microscope*

Undoubtedly close connections often exist between capsule and cell wall Thus immunologically identical polysaccharides were *found in the wall and the capsule of Bacillus megaterium* strain M (Tomcsik 1956)

With regard to the distinction between cell

FIG 12 India ink wet mounts of *Aerobacter aerogenes* (× 2 000) (*Left*) Cells with small capsules (*center*) Cells with average sized capsules (*right*) Cells with large capsules and loose slime (Duguid 1951)

wall and cytoplasmic membrane high resolution electron micrographs of sectioned non capsulated bacteria show 2 main surface layers (Figs 16 17) Generally the entire outer layer is considered to represent the cell wall the entire inner layer the cytoplasmic membrane Electron micrographs of lysed bacteria (Kellenberger and Ryter 1958 Fig 18) lend support to this view especially as the inner membrane appears as folded and consequently lacking in rigidity

Studies on isolated cell components (Salton 1961) indicate a closer association between cell wall and cytoplasmic membrane in gram negative bacteria than in gram positive ones However plasmolysis experiments (Elo 1937 Robinow 1960a) suggest just the opposite

CAPSULE (SLIME LAYER)

Morphology and Structure of the Capsule

Many procedures for the staining of bacterial capsules have been described These structures can be demonstrated very simply and reliably by suspending living bacteria in India ink (Duguid 1951) The capsules then appear as clear zones around the bacterial bodies (Fig 12) Capsules can also be visualized by adding homologous antiserum to a bacterial suspension producing the so called capsule swelling reaction (Tomcsik 1956)

The size of capsules may vary widely (Fig 12) When the bacteria are surrounded by a diffuse zone of extracellular material (Fig 12 *right*) the terms slime layer or loose slime often are used instead of the word capsule

Bacteria may lose their capsules through mutations Such loss of capsule is reflected in altered appearance of the colonies encapsulated bacteria form more or less mucoid colonies (M colonies) whereas bacteria without capsules form relatively dry colonies with a smooth or rough surface (S and R colonies) In pneumococci encapsulated bacteria usually are designated as S forms bacteria without capsules as R forms The capsules can also be removed enzymatically (Tomcsik 1956)

Most bacterial capsules seem to consist of accumulations of amorphous material However some capsules possess a definite structure Thus capsules containing banded fibrils may be observed in a strain of *Escherichia coli* (Salton 1960a) The capsule of a strain of *Bacillus megaterium* contains a skeletal structure of transverse striations condensed at the poles (Tomcsik 1956 Fig 13)

There exists a close relationship between the presence of capsule in some pathogenic bacteria and their virulence This is especially evident in the case of *Diplococcus pneumoniae Klebsiella pneumoniae* and *Bacillus anthracis* Nonencapsulated strains of these bacteria are avirulent

Chemical Composition of Capsules

Most of the substances forming bacterial capsules are polysaccharides However some capsules consist of material of a polypeptide nature and a capsule containing both polysaccharide and polypeptide is found in *Bacillus megaterium* (Tomcsik 1956) The capsule of *Pasteurella pestis* probably also consists of proteinaceous material associated with carbohydrate (Tomcsik 1956)

Table 1 shows the chemical composition of capsules of some bacteria of medical interest It can be seen that strains of the same species may possess capsules of different chemical composition These differences are reflected in the antigenic properties of the capsules (Heidelberger 1956)

CELL WALL

Methods of Study

Bacterial cell walls have a poor affinity for ordinary stains but according to Tomcsik

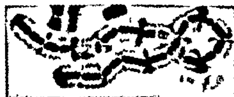

Fig 13 Capsulated cells of *Bacillus megaterium* Note transverse striations in capsule (× 2 500 phase contrast) (Tomcsik 1956)

FIG 11 Fimbriate cell of *Shigella flexneri* (× 24 000) Electron micrograph from Duguid and Wilkinson (1961)

slime layer, (2) the cell wall and (3) the cytoplasmic membrane The capsule which forms the outermost layer of the cell is difficult to define usually capsules are demonstrable by the light microscope and their removal from a bacterium does not cause the death of the organism The cell wall is commonly defined as the rigid structure which gives a bacterium its characteristic shape The cytoplasmic membrane is considered as a part of the bacterial cytoplasm It is flexible and semipermeable serving to regulate the osmotic pressure inside the cells

Physiologic, chemical mechanical or morphologic criteria have been used by various workers to define the surface layers of bacteria Since results sometimes differ depending on the criterion it is difficult to decide with certainty to which of the surface layers certain structures or chemical compounds should be assigned

The streptococcal M proteins for example can be removed enzymatically from living bacteria without killing them (Salton 1953) On this basis the M proteins could be regarded as capsular substances However the removal of these compounds does not change the morphology of streptococcal cell walls (Salton 1953 Slade 1957) Using the terminology of Wilkinson (1958), the M proteins might therefore be considered as microcapsular substances At present no conclusion can be drawn as to the precise location of the M proteins

Many gram negative bacteria lose their O antigens by nonlethal mutations Thus the O antigens might be considered as microcapsular substances since bacteria possessing these substances as a rule do not possess capsules demonstrable in the light microscope

Undoubtedly close connections often exist between capsule and cell wall Thus immunologically identical polysaccharides were found in the wall and the capsule of *Bacillus megaterium* strain M (Tomcsik 1956)

With regard to the distinction between cell

FIG 12 India ink wet mounts of *Aerobacter aerogenes* (× 2 000) (*Left*) Cells with small capsules (*center*) Cells with average sized capsules (*right*) Cells with large capsules and loose slime (Duguid 1951)

Fig 15 Electron micrograph of *Nocardia calcarea* (thin section) showing "microcapsule" cell wall and cytoplasmic membrane (× 100 000) (Glauert 1962)

the chemistry of isolated cell walls have been studied extensively The wall preparations are obtained by mechanical disintegration of the bacteria and isolation of the wall fragments by differential centrifugation of the homogenate (Salton 1960a Fig 22)

Structure and Chemical Composition of the Walls

In electron micrographs of unsectioned bacterial specimens the cell wall most often appears without any definite structure However regular patterns of approximately spherical subunits have been revealed in the walls of some bacteria (Salton 1960b Glauert 1962 Murray 1962 Fig 14) A fibrous appearance was found in walls of *Bacillus megaterium* (Salton 1960b)

Electron micrographs of sectioned organisms indicate that many or most bacterial cell walls have a multilayered structure (Figs 15 to 19) The walls of gram positive bacteria vary in thickness from 150 to more than 500 A (Glauert 1962) They are thicker than those of gram negative bacteria (thickness 100 A or less) In high resolution micrographs the walls of gram positive organisms appear to consist of 2 thin electron-dense layers separated by a wider layer of slightly less dense material (Fig 16) The walls of gram negative bacteria also appear to consist of 3 layers but in these bacteria all strata have about the same thickness (Figs 17 18) and the density of the middle layer is much lower than that of the surrounding layers

Notable differences exist between gram positive and gram negative bacteria in the chemical nature of their cell walls The composition of the walls of the former group is generally considered to be less complex al

Fig 16 Electron micrograph of *Bacillus subtilis* (thin section) showing cell wall wall septa cytoplasmic membrane mesosome ground cytoplasm and nuclear equivalent (× 95 000) (Ellerling, F A and Romig W R J Ultrastruct Res 6 540 1962)

TABLE 1 CHEMICAL COMPOSITION OF BACTERIAL CAPSULES*

ORGANISM	CLASS OF SUBSTANCE	CONSTITUENTS IDENTIFIED
Diplococcus pneumoniae type II	Polysaccharide	Glucose glucuronic acid rhamnose
Diplococcus pneumoniae type III	"	Glucose glucuronic acid
Diplococcus pneumoniae type XIV		Glucose galactose N acetyl glucosamine
Streptococcus spp groups A and C		Glucuronic acid N acetyl glucosamine
Leuconostoc mesenteroides	Polysaccharide hyaluronic acid	Glucose
Bacillus anthracis	Polypeptide	D glutamic acid
Haemophilus influen ae	Polyribophosphate	Ribose phosphate
Klebsiella spp	Polysaccharide polyuronides	Glucose galactose mannose fucose uronic acid

* Data summarized from Salton (1960a)

and Grace (1955) staining with Alcian blue gives good results However cell walls can be visualized in the light microscope without staining procedures Figure 1 G shows cells crushed in India ink The ink has penetrated into the cells replacing the protoplasm of the living organisms The cell wall thus appears as a light chambered skeleton against a dark background Evidently the walls possess a high degree of rigidity Empty unstained cell walls are also visible in the phase contrast microscope (Fig 1 H) For the study of structural details however the electron microscope must be used (Figs 14 to 19 22)

The rigidity of the cell wall can also be demonstrated by plasmolysis experiments (Elo 1937 Taubeneck 1955 Robinow 1960a Cota Robles 1963) During plasmolysis the outer shape of the cells remains unchanged whereas the protoplasm partly or occasionally completely retracts from the wall

During the last 15 years the structure and

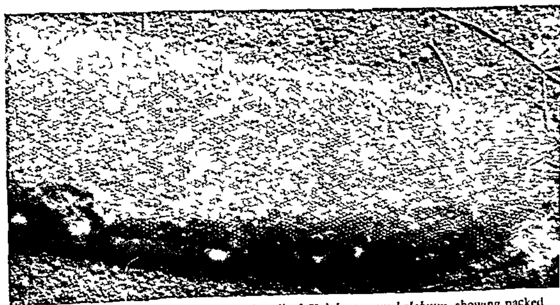

FIG 14 Electron micrograph of whole cell of *Halobacterium halobium* showing packed subunits of cell wall (× 72 500) (Salton 1960*b* from Dr A I Houwink Laboratory of Microbiology Technological University Delft)

though both groups have a so-called basal structure (Salton 1960b) in common This structure could be defined as a mucopeptide or perhaps what is more nearly correct a class of mucopeptides consisting of N acetyl hexosamine N acetyl muramic acid glutamic acid alanine and diaminopimelic acid The last mentioned compound is replaced by lysine in some bacteria e g staphylococci All of the glutamic acid and approximately half of the alanine occurs in the form of the D isomers A tentative model for a subunit of a wall mucopeptide (Salton 1962) is shown in Figure 20 The mucopeptide is generally considered to be responsible for the rigidity of the cell wall (Salton 1960b Martin and Frank 1962 Weidel Frank and Leutgeb 1963 Takeya Hisatsune and Inoue 1963 Fig 22)

Preparative and analytical data indicate that the walls of most gram positive bacteria contain polysaccharides in addition to the basal mucopeptide(s) Thus the group specific carbohydrate of group A streptococci consists primarily of rhamnose and N acetyl glucosamine (Salton 1960a) A polysaccharide consisting of N acetyl glucosamine and glucuronic acid is found in the walls of *Bacillus subtilis* (Perkins 1963) Glucose may be a constituent of the cell wall polysaccharides and is found also in another group of wall substances primarily characteristic for gram positive bacteria the teichoic acids (Baddiley 1962 Baddiley *et al* 1962 Sanderson Strominger and Nathenson 1962) Teichoic acids contain a backbone of ribitol or glycerolphosphate Glucose or N acetyl glucosamine is joined to this backbone by glucosidic linkages (Fig 21) and alanine by ester linkages Teichoic acids do not seem to contribute to the rigidity of the walls but may constitute more than 50 per cent of their dry weight

Only small amounts of lipids and proteins are found in the walls of gram positive bacteria (the streptococcal M proteins form an exception to this rule) The walls of gram negative organisms on the other hand contain proteinaceous material in addition to polysaccharides and the basal mucopeptide Moreover they contain substantial amounts of lipids and perhaps occasionally teichoic acids (Clarke and Lilly 1962)

Complexes of proteins lipids and polysaccharides constituting the bacterial O antigens can be extracted from the walls of gram negative bacteria by diethyleneglycol or some other solvents (Westphal *et al* 1958 Colobert and Creach 1961 Westphal and Luderitz 1963) The antigenic specificity is determined by the polysaccharide moiety or more specifically the terminal oligosaccharides of the polysaccharide chains The smooth (S) forms of *Salmonella* spp contain polysaccharides consisting of glucosamine and galactosamine glucose galactose mannose ribose rhamnose fucose heptoses and dideoxihexoses whereas the polysaccharides of rough (R) forms contain only glucosamine glucose galactose and heptose (Westphal and Luderitz 1963)

The complexes described in the preceding paragraph also represent the endotoxins of

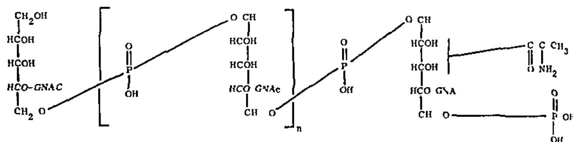

FIG 21 Structure of the teichoic acid of *Staphylococcus aureus* strain Copenhagen The polymer contains 0 5 alanine residue per ribitol the distribution of which is unknown n = 10 to 14 GNAc = acetylglucosamine (Sanderson Strominger and Natheson 1962)

gram negative bacteria It remains uncertain which component of the polysaccharide lipid protein complex accounts for the toxic properties (Westphal *et al* 1958 Westphal and Luderitz 1963 Ribi *et al* 1961)

By combining results from chemical and electron microscopic studies Martin and Frank (1962) concluded that the cell wall of *Escherichia coli* consists of 3 layers an outer lipoprotein layer an intermediate lipo polysaccharide layer and an inner layer con sisting of protein and the rigid mucopeptide (Fig 22) According to Clarke and Lilly (1962) the surface layers of gram negative bacteria apparently consist of 2 unit mem branes of the kind found in higher organisms (Robertson 1959) and a rigid layer in be tween The outer membrane the cell wall probably consists of polysaccharide lipid lipid protein the protein forming the outer most stratum This would be in accordance with the findings of Martin and Frank (1962) It would also be consistent with the appearance of sectioned cells in electron mi crographs (Murray 1962 Figs 17 18)

BIOSYNTHESIS AND FUNCTIONS OF THE CELL WALL

Figure 23 shows a tentative but widely accepted scheme for synthesis of cell wall mucopeptide (Work 1961) Penicillin and some other antibiotics interfere with this syn thesis Usually this process causes the death of the organisms but under controlled condi tions aberrant growth forms the so-called bacterial L forms (Kandler and Kandler 1960 Timakov and Kagan 1961 Kliene-berger Nobel 1962) appear replacing the normal cells Chemical and electron micro scopic studies indicate that many of these bacterial L forms contain no or almost no cell wall constituents (Thorsson and Weibull 1958 Freimer Krause and McCarty 1959 Panos Barkulis and Hayashi, 1959 Kandler and Kandler, 1960 Morrison and Weibull 1962 Tulasne, Minck and Kirn 1962) L form colonies consist of soft elements of a spherical or irregular shape

The biosynthesis and the structure of the cell wall have been reviewed in detail by Salton (1960a and b 1961 1962) Work (1961) Strominger (1962) Rogers (1963) and Perkins (1963)

The cell wall protects the cell very effi ciently from mechanical injury and also pre vents the bacteria from bursting osmotically in hypotonic media The cell wall seems metabolically to be relatively inert As yet no enzyme has been unequivocally localized in it Moreover normal bacterial cells and L forms or protoplasts have roughly the same biochemical capabilities (Kandler and Kandler 1960 McQuillen 1960 Weibull and Beckman 1960 Panos 1962) From one point of view the cell wall can be said to have an unfavorable effect on the survival capacity of the bacterial cell it contains the so-called phage receptors (Salton 1960a) onto which bacterial viruses attach them selves at the beginning of their attack on the host organism The role of the cell wall in sexual conjugation is not clear (Bladen 1963)

BACTERIA NORMALLY LACKING A RIGID CELL WALL

Evidence derived from microscopic and chemical studies indicates that the *Myco*

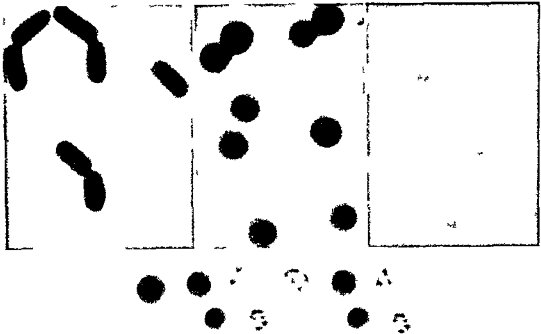

FIG 25 Cells protoplasts and ghosts of *Bacillus megaterium* (× 3 000 phase con trast) (*Top row*) Whole cells protoplasts and ghosts of the M strain (*Bottom*) Proto plasts and ghosts of the KM strain the protoplast on the extreme left lysed between the exposures forming a ghost (The photographs in the top row from Stanier R Y Doudoroff M and Adelberg E A The Microbial World ed 2 Englewood Cliffs Prentice Hall 1963)

plasmatales do not possess a cell wall structure similar to that found in most bacteria (Edwards and Fogh 1960 van Iterson and Ruys 1960 Morrison and Weibull 1962 Fig 24) This is in accordance with the fact that the *Mycoplasmatales* are very easily distorted by mechanical forces (Liebermeister 1960 Klieneberger Nobel 1962 Weibull and Lundin 1963) The *Myxobacterales* seem to possess a cell wall of normal thickness but lacking in rigidity (Voelz and Dworkin 1962)

CYTOPLASMIC MEMBRANE

EXISTENCE OF A CYTOPLASMIC MEMBRANE IN BACTERIA

Plasmolysis experiments carried out mainly on gram negative bacteria offered the first evidence suggesting that bacteria possess a semipermeable membrane surrounding the bacterial protoplasm but located inside the cell wall (Elo 1937 Robinow 1960) Other permeability studies (Stahelin 1954 Weibull 1955 Mitchell and Moyle 1956a and b 1957 Gilby and Few 1959) electron microscopy and staining experiments (Robinow and Murray 1953) also indicated the presence of a semipermeable membrane inside the cell wall of gram positive bacteria These bacteria can be plasmolyzed only with difficulty (Knaysi 1951 Robinow 1960a)

In a few gram positive bacteria the cell wall can be completely dissolved by the enzyme lysozyme If this process is conducted in a medium of sufficiently high osmotic pressure the dissolution of the cell wall does not cause the disintegration of the internal structure of the cell and naked protoplasts are thus released (Weibull 1958 McQuillen 1960 Martin 1963) When the osmotic pressure is lowered the protoplasts disintegrate Conversion of an individual protoplast into a ghost of approximately the same

CYTOPLASMIC MEMBRANE

EXISTENCE OF A CYTOPLASMIC MEMBRANE IN BACTERIA

Plasmolysis experiments carried out mainly on gram negative bacteria offered the first evidence suggesting that bacteria possess a semipermeable membrane surrounding the bacterial protoplasm but located inside the cell wall (Elo 1937 Robinow 1960) Other permeability studies (Stahelin 1954 Weibull 1955 Mitchell and Moyle 1956a and b 1957 Gilby and Few 1959) electron microscopy and staining experiments (Robinow and Murray 1953) also indicated the presence of a semipermeable membrane inside the cell wall of gram positive bacteria These bacteria can be plasmolyzed only with difficulty (Knaysi 1951 Robinow 1960a)

In a few gram positive bacteria the cell wall can be completely dissolved by the enzyme lysozyme If this process is conducted in a medium of sufficiently high osmotic pressure the dissolution of the cell wall does not cause the disintegration of the internal structure of the cell and naked protoplasts are thus released (Weibull 1958 McQuillen 1960 Martin 1963) When the osmotic pressure is lowered the protoplasts disintegrate Conversion of an individual protoplast into a ghost of approximately the same

diameter can be followed in the light microscope Essentially, these ghosts represent cytoplasmic membranes containing varying amounts of adherent protoplasmic material (Fig 25)

Modern technics for electron microscopy make it possible to obtain pictures clearly indicating the presence of cytoplasmic membranes in bacterial cells (Figs 15 to 19)

Structure and Chemical Composition of the Plasma Membrane

The cytoplasmic membrane appears in high resolution electron micrographs of sectioned bacteria as a unit membrane (Robertson 1959) consisting of 2 dense strata separated by a less dense layer (Brown Drummond and North 1962 Glauert 1962 Hughes 1962 Murray, 1962 Fig 16) The thickness of the membrane is approximately 75 A Several electron micrographs have been published showing invaginations in the cytoplasmic membrane These invaginations may become deep and wide giving rise to intracytoplasmic bodies still connected with the cytoplasmic membrane (Figs 16 and 19) These structures have been named peripheral bodies chondrioids and mesosomes (Glauert 1962 Murray, 1962 Kawata 1963) and they have been compared with the mitochondria of protozoa and higher organisms (Giesbrecht 1960)

The chemical composition of the cytoplasmic membrane of various bacteria notably *Bacillus megaterium Micrococcus lysodeikticus* and *Streptococcus faecalis* has been studied in some detail Most analyses have been carried out on preparations obtained by lysing bacteria with lysozyme and isolating the membraneous ghosts by differential centrifugation (Gel man Zhukova and Oparin 1959 McQuillen 1960 Salton 1961, Hughes 1962 Shockman *et al* 1963) Some information on membrane composition has also been obtained from studies on mechanically or chemically disrupted bacteria (Mitchell and Moyle 1956a Mathews and Sistrom 1959 Marr 1960a Brown, Drummond and North 1962 Robrish and Marr 1962) It is difficult to assess the extent to which the ghosts or cell fractions represent pure cytoplasmic membranes other cytoplasmic structures, e g the mesosomes mentioned above may be present in the ghosts (Robrish and Marr 1962)

The main constituents of the cytoplasmic membrane seem to be protein (40 to 70% dry weight) and lipid (15 to 40%) Mainly phospholipid containing little, if any, nitrogen has been recovered In some membranes considerable amounts of carbohydrate have also been found (10 to 20%) Substantial amounts of RNA reported in some membrane preparations could represent protoplasmic contamination

Cell wall constituents such as diaminopimelic acid and hexosamine were not found in the membranes of *B megaterium* similarly D amino acids and rhamnose were absent from the membranes of *S faecalis* According to Shockman *et al* (1963) the chemical composition of the membrane of *S faecalis* varied quantitatively with the cultural conditions Freimer (1963) has described recently the chemical composition and the serologic properties of membranes isolated from group A streptococci

Bacterial ghosts' and particulate fractions consisting of the combined surface layers of bacteria exhibit enzymatic activity (Sheinin 1959 Marr 1960a and b Brown 1961 Salton 1961 Abrams and McNamara 1962 Burrous and Wood 1962 Campbell Hogg and Strasdine 1962 Gelman and Lukayanova 1962 Hughes 1962 Ishikawa and Lehninger 1962 Robrish and Marr 1962 Weibull Greenawalt and Low, 1962) Some of these enzymes e g cytochromes and succinic dehydrogenase seem to be associated exclusively with the cytoplasmic membranes or with intracytoplasmic bodies (mesosomes) connected with this membrane (Vanderwinkel and Murray 1962) The localization of enzymes in or near the cytoplasmic membrane has also been demonstrated by topical inactivation of enzymes in whole bacteria (Preiss and Pollard 1961) and by microscopic observations on the sites of tetrazolium and tellurite reduction in normal bacterial cells and L forms (Nermut 1960 Mudd *et al* 1961) On the other hand some enzymes are found mainly in the protoplasmic fraction and others are apparently present in both the membrane and the protoplasm On the whole the cytoplasmic membrane seems to

FIG 26 Electron micrograph of ribosomes from *Escherichia coli* (× 200 000 negative staining) Two types of ribosomes are visible monomers (70 S particles) consisting of 2 unequal subunits and dimers (100 S particles) (Huxley and Zubay 1960)

be rich in enzymes and probably plays an important metabolic role as well as being a regulator of the osmotic pressure inside the bacterial cell These functions of the cytoplasmic membrane have been discussed comprehensively by Mitchell (1961 1962)

CELL DIVISION

The cell division process has been studied with the light microscope (Knaysi 1951 Bisset 1954 Clark Webb and Chance 1957 Robinow 1960a) and with the electron microscope (Chapman 1959 1960 Conti and Gettner 1962 Glauert 1962) In most gram positive bacteria a ring of cell wall material forms and grows inward to form a complete cross wall before division occurs (Fig 16) Perhaps the cytoplasmic membrane (Roth Lewis and Williams 1960) or so called peripheral bodies (Glauert 1962) or other intracytoplasmatic membrane systems (Imaeda and Ogura 1963) play a role in this process In gram positive rod shaped organisms the separation of the daughter cells usually does not follow immediately after the completion of the cross wall consequently chains or aggregates of cells are formed (Figs 1 F G and H)

Cell chains are found less frequently in gram negative bacteria These bacteria usually divide by constriction without the formation of cross walls (Fig 17) However cross wall formation in *Escherichia coli* has been described recently by Conti and Gettner (1962)

CYTOPLASM

The bacterial protoplast can be divided into 3 parts the cytoplasmic membrane the cytoplasm which lacks DNA but is rich in RNA and the nuclear equivalent which contains all or almost all of the DNA of the cell

GROUND CYTOPLASM

In electron micrographs of sectioned bacteria (Figs 16 and 17) the cytoplasm usually appears to be homogeneous and finely granular The size and the shape of the cytoplasmic granules as a rule termed ribosomes are difficult to ascertain from inspection of sectioned material but in most cases they appear to be roughly spherical with a diameter of 100 to 300 Å (Murray 1960 Glauert 1962 Brieger 1963) The appearance of the sectioned cytoplasm seems to vary depending on the cultural conditions under which the bacteria are grown (Costerton Murray and Robinow 1961 Vanderwinkel and Murray 1962)

Detailed information concerning the nature of bacterial ribosomes has been obtained from electron microscopic chemical and physicochemical studies on material isolated from disintegrated cells Thus in extracts of *Escherichia coli* Tissieres *et al* (1959) Hall and Slayter (1959) and Huxley and Zubay (1960) found particles having sedimentation coefficients of 30 50 70 and 100 S The particles contain 80 to 90 per cent of the RNA of the cells The 100 S particles represent dimers of the 70 S particles and each 70 S particle consists of one 50 S and one

30 S component (Fig 26) The 50 S particles are approximately spherical having a diameter of approximately 150 A and a molecular weight of 1,800 000 The recovery of the various particle aggregates depends on the concentration of Mg^{++} ions in the suspending medium According to Bowen *et al* (1961), mainly 50 S and 30 S particles are present in living cells of *E coli* and *Bacillus cereus*

The main components of the *E coli* ribosomes are RNA (Kurland 1960) and protein (Waller and Harris 1961) According to Zubay and Wilkins (1960) the nucleic acid and the protein of the ribosomes have an appreciable degree of structural independence as in nucleohistones

Ten to 20 per cent of the bacterial RNA the so-called soluble RNA has a relatively low molecular weight approximately 25,000 and is not bound to protein (Tissières 1959) This RNA is also termed transfer RNA since it transports amino acids to the sites of protein synthesis the ribosomes in the bacterial cells (Hunter and Godson 1961 Perutz 1963 Zubay 1963) Another kind of RNA messenger RNA carries genetic information from DNA to the ribosomes Messenger RNA is metabolically unstable and has a molecular weight of 250 000 or more (Risebrough Tissières and Watson 1962) It constitutes at the most a few per cent of the total RNA of the cell which in turn represents 10 to 25 per cent of the bacterial dry weight depending on the physiologic age of the organisms and the cultural conditions

The major part of the cytoplasmic proteins which are not associated with nucleic acids or located in the cytoplasmic membrane have sedimentation coefficients between 3 and 6 S (Schachman Pardee and Stanier 1952 Koenig *et al* 1959) Most of the enzymic activities of the ground cytoplasm seem to be located in these proteins However nucleases have been found in the ribosomes of *E coli* and *Azotobacter vinelandii* and in the ribosomes of the former organism a peptidase has also been demonstrated (Marr, 1960b)

A number of low molecular weight substances such as coenzymes vitamins nucleotides, peptides amino acids and sugars are also present in the ground cytoplasm

Bacterial cytoplasm, which contains approximately 80 per cent water seems to represent a sol rather than a gel Thus the ultracentrifugation experiments of King and Beams (1942) showed that the cytoplasmic inclusions of *Spirillum volutans* were displaced to the dependent parts of the cells upon centrifugation at 400 000 G When the cells were removed from the centrifugal field, the inclusions redistributed within 30 to 60 minutes It has also been noted that the lipid granules of *Bacillus megaterium* cells change their intracellular position rapidly (Robinow 1960a)

There are indications that the salts and other low molecular weight compounds of the cytoplasm exist to a large extent in a free solution instead of being bound to the cytoplasmic macromolecules Thus Mitchell and Moyle (1956a) found a good agreement between the values for the intracellular osmotic pressures of *Staphylococcus aureus* and *E coli* obtained from direct measurements and from estimations of the contents in the cell of low molecular weight compounds Similarly Sistrom (1958) reported that galactosides enzymatically transported into *E coli* cells exhibited an intracellular osmotic pressure that could be explained only if the accumulated galactosides existed in free solution

Cytoplasmic Inclusions

Bacterial cytoplasm does not contain organelles comparable with the endoplasmic reticulum Golgi apparatus or lysosomes seen in mammalian cells

In bacteria of medical interest the following kinds of inclusions are found lipid inclusions (Burdon 1946) granules of glycogen and starch (Murray 1960) and metachromatic granules In some bacteria sulfur granules and protein crystals occur (Murray 1960 Robinow 1960a) The presence in bacteria of vacuoles containing gas or liquids has also been demonstrated (Houwink 1956 Murray 1960 Brieger 1963)

Metachromatic granules (Fig 2) owe their name to the fact that certain dyes e g toluidine blue and methylene blue change color when combining with these granules Metachromatic inclusions are also named

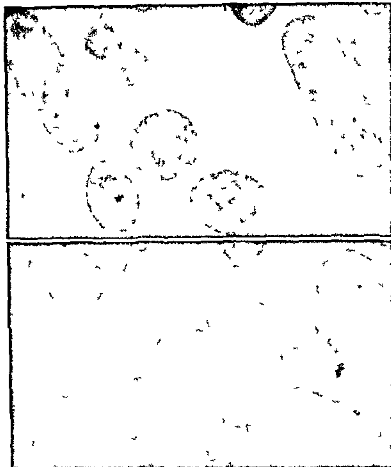

FIG 27 Electron micrographs of *Escherichia coli* cells (thin sections) (*Top*) Cells containing 17 4 per cent and (*bottom*) 4 5 per cent glycogen (× 30 000) (Holme and Cedergren 1961)

volutin because they occur prominently in cells of *Spirillum volutans* Histochemical observations and chemical analyses on material extracted from bacteria indicate that the main constituent of the metachromatic granules is polymetaphosphate (Winkler 1956 Sall Mudd and Takagi 1958 Murray 1960) The metachromatic granules have been identified with nuclear equivalents and intracellular reduction sites However these identifications are evidently not tenable (Glauert and Brieger 1955 Winkler 1956 Mudd Takeya and Henderson 1956)

Lipid granules seem to be the most common type of cytoplasmic inclusion of lipid nature Chemical analyses indicate that these granules contain poly β hydroxybutyric acid (Hayward Forsyth and Roberts 1959 Doudoroff and Stanier 1959 Wilkinson 1959 Murray 1960 Slepecky and Law 1961 Fig 1 B C and E) and some other lipid in addition Their sudanophilic character probably should be attributed to the latter component (Wilkinson, 1959)

The accumulation of glycogen granules in *E coli* cells has been studied in some detail by Holme and Cedergren (1961) A great number of low density areas (holes) are seen in electron micrographs of cells rich in glycogen whereas in cells containing little glycogen only few holes are seen (Fig 27) Cells rich in glycogen show heavy staining with the periodic Schiff reagent

Cells of *Clostridium* spp accumulate a starchlike substance named granulose at the time of sporulation (Murray 1960 Robinow 1960a)

The cultural conditions and the physiologic age of the organisms greatly influence the occurrence of cytoplasmic inclusions in

Fig 28 *Bacillus cereus* stained according to Feulgen Note dark nuclear equivalents (× 3 500) (Robinow 1960a)

bacteria It has been suggested that these inclusions represent waste products or storage material In the case of poly β hydroxybutyric acid evidence favoring the latter view was presented by Wilkinson (1959 1963) and Doudoroff and Stanier (1959) The findings of Holme and Palmstierna (1956) indicate that glycogen represents storage material in *Escherichia coli* Sall Mudd and Takagi (1958) found that polymetaphosphate was used up during periods of cell division in synchronized cultures of *Corynebacterium diphtheriae*

NUCLEAR EQUIVALENT

Existence and Methods of Study

Clear evidence for the existence of nuclear bodies in bacteria was not presented until comparatively recently mainly because the importance of selecting appropriate bacterial specimens for the experimental work was not well understood and because most methods for observing or staining nuclei in higher organisms are unsuitable for bacteria However in the late 1930s positive results were obtained by Feulgen staining a reaction considered to be specific for DNA (Fig 28) In later studies use was made of other dyes which stain nuclear material intensely For example the nuclear bodies fluoresce specifically when stained with acridine orange (Robinow 1956 1962 Hayes 1960 Kellenberger 1960 Brieger 1963)

Usually the nuclear equivalents of living bacteria are seen poorly or not at all in the light microscope However when the organisms are suspended in a medium of a high refractive index often the nuclear bodies can be observed in the phase contrast microscope and their division can be followed (Fig 29)

Early electron micrographs did not give very informative pictures of the nuclear equivalents In electron micrographs of bacteria sectioned fixed and embedded according to improved methods a central region filled with delicate fibers can be seen (Figs 16 and 17) Comparisons with autoradiographic and light microscopic material show that this region contains the nuclear material (Birch Andersen 1955 Caro and Tubergen 1962 Fig 30)

Chemical analyses on whole bacteria and isolated nuclear bodies indicate that all or almost all of the bacterial DNA is located in the nuclear region (Hayes 1960)

Fig 29 Division of cells and nuclear equivalents in *Escherichia coli* (× 2 000 phase contrast) Growth medium contained 20 per cent gelatin Time between exposures 3 to 9 minutes (Dr D J Mason Department of Microbiology The Upjohn Company Kalamazoo Mich)

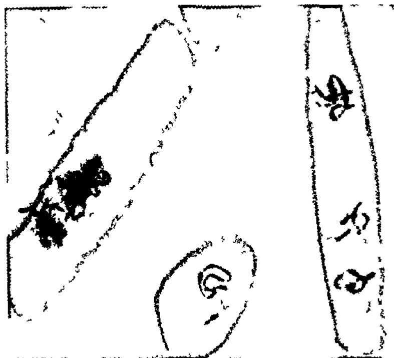

FIG 30 Thin sections of *Bacillus subtilis* labeled with (H^3) thymidine The photographic grains seem closely associated with the nuclear regions (× 38 000) (Caro and Tubergen 1962)

MORPHOLOGY STRUCTURE AND CHEMICAL COMPOSITION

The light microscopic appearance of the nuclear regions of bacteria is extremely variable Thus they may appear as round bodies dumbbells axial filaments or scattered granules connected with fine strands This variation is often related to cultural conditions or the fixation methods used but it may also be ascribed to generic or specific differences In any case all workers agree that chromosomes of the morphology characteristic for higher organisms do not occur in bacteria nor is there a mitotic apparatus (Hayes 1960 DeLamater 1962)

The fine structure of nuclear bodies in bacteria has been well studied with the electron microscope No membrane is seen between the nuclear bodies and the cytoplasm (Figs 16 and 17) This is the main reason along with the absence of mitosis for the frequent use of the term nuclear equivalent instead of nucleus when referring to bacteria. Nuclear material in bacteria commonly consists of fibrils 20 to 60 A thick which fill the entire nuclear region (Figs 16 and 17) The pictures published by Giesbrecht (1962) suggest that in some bacteria at least the fibrils are organized in coils similar to those found in the chromosomes of some protozoa Close associations between the nuclear bodies and mesosomes have also been described (Giesbrecht 1962 Robinow 1962)

A wealth of genetic data (see chapter on bacterial genetics) indicates that the genes of *Escherichia coli* are located on a single chromosome which usually forms a closed loop A morphologic confirmation of this genetic model has been presented by Cairns (1963) who prepared autoradiographs of isolated nuclear material previously labeled with (H^3) thymidine (Fig 31) The length of the chromosome is approximately 1 000 μ which is in accordance with genetic data A chromosome of this length must necessarily be coiled or bent repeatedly when located inside the cell Hypothetical models explaining the structure of the nuclear bodies have been presented by Kellenberger (1960) Schlote (1961) and Robinow (1962)

The findings of Kleinschmidt *et al* (1961) Cairns (1963) and others indicate that the bacterial DNA like the DNA of higher organisms exists in the form of a fiber which on the molecular level has the double helix structure presented by Watson and Crick

Fig 28 *Bacillus cereus* stained according to Feulgen Note dark nuclear equivalents (× 3 500) (Robinow 1960a)

bacteria It has been suggested that these inclusions represent waste products or storage material In the case of poly β hydroxybutyric acid evidence favoring the latter view was presented by Wilkinson (1959 1963) and Doudoroff and Stanier (1959) The findings of Holme and Palmstierna (1956) indicate that glycogen represents storage material in *Escherichia coli* Still Mudd and Takagi (1958) found that polymetaphosphate was used up during periods of cell division in synchronized cultures of *Corynebacterium diphtheriae*

NUCLEAR EQUIVALENT

Existence and Methods of Study

Clear evidence for the existence of nuclear bodies in bacteria was not presented until comparatively recently mainly because the importance of selecting appropriate bacterial specimens for the experimental work was not well understood and because most methods for observing or staining nuclei in higher organisms are unsuitable for bacteria However in the late 1930s positive results were obtained by Feulgen staining a reaction considered to be specific for DNA (Fig 28) In later studies use was made of other dyes which stain nuclear material intensely For example the nuclear bodies fluoresce specifically when stained with acridine orange (Robinow 1956 1962 Hayes 1960 Kellenberger 1960 Brieger 1963)

Usually the nuclear equivalents of living bacteria are seen poorly or not at all in the light microscope However when the organisms are suspended in a medium of a high refractive index often the nuclear bodies can be observed in the phase contrast microscope and their division can be followed (Fig 29)

Early electron micrographs did not give very informative pictures of the nuclear equivalents In electron micrographs of bacteria sectioned fixed and embedded according to improved methods a central region filled with delicate fibers can be seen (Figs 16 and 17) Comparisons with autoradiographic and light microscopic material show that this region contains the nuclear material (Birch Andersen 1955 Caro and Tubergen 1962 Fig 30)

Chemical analyses on whole bacteria and isolated nuclear bodies indicate that all or almost all of the bacterial DNA is located in the nuclear region (Hayes 1960)

Fig 29 Division of cells and nuclear equivalents in *Escherichia coli* (× 2 000 phase contrast) Growth medium contained 20 per cent gelatin Time between exposures 3 to 9 minutes (Dr D J Mason Department of Microbiology The Upjohn Company Kalamazoo Mich)

these organelles within the cytoplasm usually one spore is formed in each cell Several morphologic spore types exist which may be used for taxonomic purposes Thus there exist spherical ellipsoidal and cylindrical spores which may be located terminally subterminally or centrally in the mother cell (the sporangium) Spores may have a diameter greater than that of the vegetative cells causing the spore forming part of the organisms to bulge (Fig 32) The spores have a high refractive index and are thus easily recognized under the light microscope They stain only after heating but once stained tend to retain the dye to a far greater extent than vegetative cells

The structure of the endospore varies somewhat from one species to another but generally the central part of the spore the spore core appears without much structural detail in electron micrographs (Fig 33 C) The core is surrounded by a double membrane the spore wall or spore cytoplasmic membrane (SM) Outside this membrane is a layer named the cortex (CX) which in turn is surrounded by 1 or 2 spore coats (IC and OC) The inner spore coat often is laminated The spore coats may be covered by a so-called exosporium The exosporium and the outer spore coat often are separated from each other either completely or at the poles of the spore (Robinow 1960b Tomcsik 1962)

The chemical composition of bacterial spores differs in many respects qualitatively or quantitatively from that of the corresponding vegetative cells The most striking difference is represented by the high content (approximately 10%) of dipicolinic acid (pyridine 2 6 dicarboxylic acid) in spores Vegetative cells are devoid of this compound (Halvorson 1962) The water content of spores as compared with that of vegetative cells has been investigated repeatedly but there is some discrepancy in the results obtained Measurements of the refractive index of spores indicate that they contain only 10 to 20 per cent of water whereas according to direct estimation of their moisture content and permeability measurements the difference in water content between spores and vegetative cells is not very marked (Black and Gerhardt 1962 Halvorson 1962)

Mucopeptide material similar to that found in walls of vegetative cells is also found in spores It is probably located in the cortex The spore coats seem to contain chiefly proteinaceous material (Warth Ohye and Murrell 1963)

Many enzymes have been found in bacterial spores (Halvorson 1962)

Marked changes occur in the enzyme pattern during formation of spores (sporulation) Thus cytochromes are not found in spores of *Bacillus* spp whereas vegetative cells are rich in these enzymes

Serologic investigations (Halvorson 1962 Tomcsik 1962) show that antisera prepared against surface structures of *Bacillus* spores do not react with the corresponding vegetative cells

The sporulation process has been characterized in considerable detail from the morphologic point of view (Fitz James 1960 Robinow 1960b Ohye and Murrell 1962 Young and Fitz James 1962) The first rec

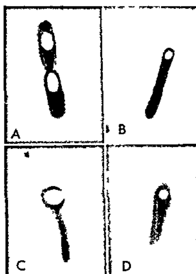

FIG 32 Spore forming bacteria (× 3 000 phase contrast) (A) *Bacillus megaterium* with central and terminal ellipsoidal spores (B) and (C) *Clostridium* spp with terminal spherical spores (D) An unidentified bacterium with a terminal spherical spore

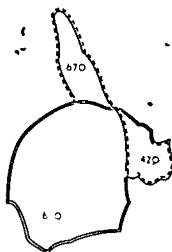

Fig 31 Autoradiograph of dividing *Escherichia coli* chromosome labeled with (H^3) thymidine for 2 generations Length of chromosome approximately 1 100μ (length of scale 100μ) In part of the chromosome only one DNA strand is labeled in part both strands (see explanatory drawing) (Cairns J Sympos Cold Spring Harbor *28* 43-46 1963)

(1953) Chemical components other than DNA have not yet been definitely localized in the nuclear equivalents of bacteria Analyses carried out on isolated nuclear bodies of *Bacillus megaterium* (Spiegelman Aronson and Fitz James 1958 Ezekiel 1961) indicate that they may also contain RNA and protein According to Spiegelman Aronson and Fitz James the nuclear protein represents a core around which the DNA is layered On the other hand Wilkins and Zubay (1959) concluded that the DNA of *E coli* unlike the DNA of higher organisms probably is not bound to protein

BACTERIAL RESTING FORMS

Endospores

The formation of endospores is especially characteristic for the genera *Bacillus* and *Clostridium* The vegetative cells develop

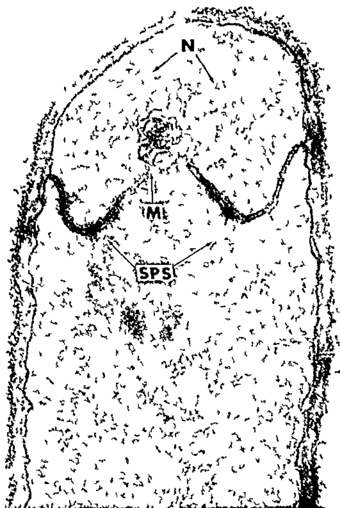

FIG 35 Electron micrograph of *Bacillus coagulans* (thin section) showing a stage in the sporulation process (× 170 000) SPS = spore septum M = mesosome N = nuclear material (Ohye and Murrell 1962)

ognizable step consists of an invagination of the sporangial cytoplasmic membrane (Fig 34 A) In this way a pocket is formed which contains the nuclear material of the future spore and some cytoplasm (Fig 34 B) The intrusions of the cytoplasmic membrane come into contact with the nuclear material and a mesosome appears in the same region (Fig 34 B Fig 35) When the cytoplasmic septum or spore septum has completely traversed the cell (Fig 34 D) it begins to bulge (Fig 34 E) and 2 or 3 mesosomes appear outside the developing spore (Fig 34 F to H) The later stages of the sporulation process are charactertized by deposition of cortical material between the 2 layers of the spore septum The high refractility of the spore develops at this stage The inner layer of the spore septum eventually forms the spore plasma membrane (spore wall) The outer layer develops into the spore coats and the exosporium

The first step in the germination process which gives rise to a new vegetative cell is a loss of refractility and swelling of the spore The young vegetative cell then extrudes through the bursting spore coats The wall of this cell seems to be the former spore wall Electron micrographs show that in the core of the germinating spore regions appear containing nuclear material of the kind found in vegetative cells Simultaneously the cytoplasm becomes distinctly granular (Robinow 1960b)

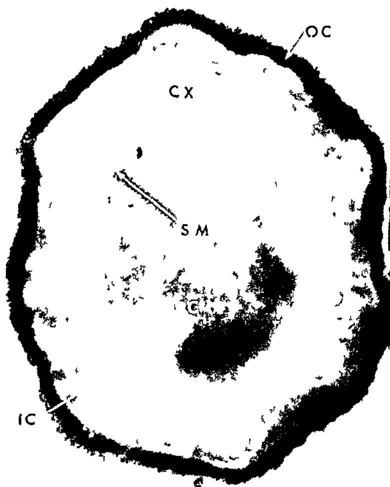

FIG 33 Electron micrograph of a mature spore of *Bacillus coagulans* (thin section) Spore heated for 8 minutes at 110 C (× 90 000) The micrograph shows the spore core (C) spore cytoplasmic membrane or spore wall (SM) cortex (CX) spore cytoplasmic membrane or spore wall (SM) cortex (CX) inner spore coat (IC) and outer spore coat (OC) (Dr D F Ohye CSIRO Division of Food Preservation Ryde New South Wales Australia)

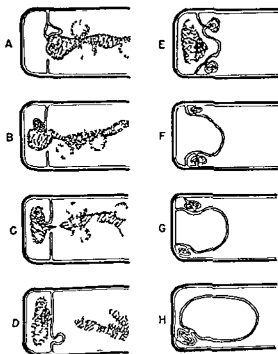

FIG 34 A diagrammatic representation of the early stages in the sporulation process in bacilli (Fitz James *1960) For explanations see text*

teria visible in the ordinary light microscope the preparation is treated with a counterstain e g neutral red safranin or Bismarck brown

Many theories have been advanced to explain the Gram stain reaction It has often been proposed that the dye iodine complex is bound to some specific compound in the bacterial cells A number of substances have been discussed in this connection especially nucleic acids lipids and proteins Some workers have assumed that gram positive organisms have a lower isoelectric point than the gram negative ones and consequently a stronger affinity to the primary basic Gram stain

However it has become increasingly clear that the Gram stain reaction cannot be explained in simple chemical or physicochemical terms The structural architecture of the bacterial cell must also be taken into account The most recent investigations (Salton 1963 Scherrer 1963a and b) point to the permeability of the cell wall as being of decisive importance Thus the wall of gram positive organisms becomes largely impermeable to low molecular weight compounds when the organisms are suspended in 70 to 100 per cent alcohol Thus probably the alcohol soluble dye iodine complex is trapped within the wall in gram positive bacteria with the consequence that the cells remain stained In gram negative organisms on the other hand the complex rapidly leaks out through the wall

It should be emphasized that there is no strict partition line between gram positive and gram negative bacteria the term gram variable is often encountered Many gram positive organisms tend to become gram negative with increasing physiologic age

The Acid Fast Stain

Certain bacteria especially *Mycobacterium* spp are not penetrated readily by ordinary dyes However when they are treated with a solution of a phenylmethane dye (usually basic fuchsin) in aqueous phenol preferably in combination with heating staining is achieved Once stained the mycobacteria retain the dye even when treated with dilute mineral acid hence the term acid fast

It has been assumed (Lamanna and Mallette 1959) that phenylmethane dyes in combination with phenol are more soluble in the milieu provided by the cell constituents of mycobacteria than in the decolorizers used This solubility might be due to certain lipids present in mycobacteria Mycobacteria with crushed walls lose their acid fastness probably the intact wall prevents the extraction of dye from the cells by the decolorizer

Cysts and Conidia

The cysts do not develop within the cyto plasm but arise by a rounding up of the en tire mother cell The cysts of *Azotobacter* spp are covered by a multi layered envelope outside the ordinary cell wall (Tchan Birch Andersen and Jensen 1962) Cysts or cyst like forms have also been described in spiro chaetes (DeLamater *et al* 1951) and spi rilla (Williams and Rittenberg 1956)

The formation of conidia or conidiospores i e resting forms produced at the end of filamentous cells is especially characteristic for the family of *Streptomycetaceae* With re gard to formation and the structure the conidia resemble bacterial cysts rather than endospores (Glauert 1962)

Intracellular Granules and Filterable Forms

Many workers have described small gran ular elements found in bacterial cultures either free or inside other bacterial forms (Klieneberger Nobel 1951 1962 Bisset 1955) These granules often pass filters which normally retain bacteria It has been assumed that they have a reproductive func tion but this view has been disputed (Kellen berger Liebermeister and Bonifas 1956 Weibull 1963)

BACTERIAL STAINS

General

Most of the staining methods mentioned in the preceding sections specifically stain certain subcellular components of the bac teria e g the nuclear equivalents These methods are used only to a limited extent in diagnostic work However other staining procedures such as the Gram staining tech nic are of great value for diagnostic pur poses When these methods are applied either the entire bacterial cell (or rather the protoplast) is stained or it is not stained at all depending on the taxonomic position of the species studied Certain simple com pounds, e g methylene blue and basic fuch sin stain almost all kinds of bacteria and are used to detect bacteria in general

Simple Stains

The main protoplasmic constituents of all bacteria are negatively charged except at rather low pH values Thus stains owing their specific light absorption to colored positive ions are well suited for staining most bac terial cells The practical performance of these staining procedures and of more com plicated staining technics is described in bacteriologic manuals (Conn 1957 Cruick shank 1960)

The Gram Stain

The Gram staining procedure (Bartolo mew and Mittwer 1952 Scherrer, 1963a) consists of 5 steps

1 The cells are fixed Heat fixation is the standard method but the method of fixation is not of decisive importance for the result of the staining

2 The cells are stained with the so-called primary Gram stain The standard dye used is crystal violet (hexamethyl triamino tri phenylmethane hydrochloride) Homologues of this dye (methyl violets) and some other dyes can also be used but no compound has been found which is superior to crystal violet The primary stain is fixed to both gram positive and gram negative bacteria The dye seems to be distributed uniformly in the cyto plasm (Tchan 1963)

3 The bacteria are mordanted with an *iodine potassium iodide solution This causes the formation of a complex which is insolu* ble in water of primary stain and iodine The *mordanting cannot be carried out before the* application of the primary stain

4 A decolorizing agent is applied to the stained and mordanted preparation This causes an extraction of the dye iodine com plex from the group of bacteria which is called gram negative whereas in the gram positive bacteria the complex is retained

Usually 70 to 100 per cent alcohol is used as decolorizer Prolonged treatment with de colorizer also extracts the dye iodine com plex from gram positive organisms Thus the difference between gram positive and gram negative bacteria is of a quantitative rather than qualitative nature

5 In order to render gram negative bac

Bacterial Genetics

Bacteria generally increase their number by the division of the cell body into two Following a period of growth both daughter cells can divide further By subsequent growth and divisions this can give rise to an enormous number of organisms in a brief period of time Barring an occasional genetic accident i e a mutation all of the descendants of a single bacterium will be identical with respect to all of the characteristics of the original ancestor The material components of the individual organisms within a bacterial culture are associated only up to the moment of cell division Therefore the members of the bacterial community are in *complete isolation one from the other with* no avenue of communication

Up until a little over a decade ago the above description would have been sufficient to account for the events of bacterial multiplication Since that time it has been found that for some bacteria there are channels of communication between the organism through which may pass information of the most useful sort—genetic information Genes (those factors which specify the properties *of an organism*) can sometimes travel either in large or small blocs from bacterium to bacterium The advantage of gene transfer is that two lines may *on contact reassemble* their features in such a way as to synthesize an organism more highly adapted to a particular environment In higher forms gene exchange occurs by sexual reproduction In bacteria, as we shall see, a number of different mechanisms for gene transfer have been found These different kinds of mechanisms for gene transfer in bacteria may represent evolutionary experiments for the *development of gene transfer systems*

The sciences of bacteriology and genetics were born some 100 years ago They proceeded to develop quite independently of each other until a marriage that was most fruitful for both sciences was made in the middle forties In a sense it was a marriage of desperation each science needed the other The problem of bacterial variation plagued a rational approach to the control of bacteria and the understanding of fundamental bac*terial growth processes In genetics the* formal gene had been described located on the chromosome and carefully mapped The problems of the chemical nature of genetic material and how it functioned were unapproachable with the then current technics

This is not to imply that there were no attempts at a genetics of bacteria for microbiologists pondered on the mechanism of variation but since the organisms seemed to reproduce solely by vegetative growth both the microbiologists and the geneticists saw no rational approach to the problem

Consideration of any biologic organism *and its hereditary mechanism leads to two* different points of view One, analogous to the genetic system that has been described for *higher forms states that an organism* has a specific well isolated unit of genetic material which contains the essential in

formation for the cell syntheses and growth The second point of view which held sway for some time in microbiology despite the lack of precedent is that each subcellular unit is responsible not only for its own function but also for its own reproduction

The latter hypothesis is necessarily vague as it is never clear to what level of cellular organization it refers—organelle substructure molecule or atom Also arising from the second point of view is the idea that variation is due to the direct action of the environment on the unit which is responsible for the particular trait in question Resistance to a drug is due to the direct action of the drug on some subcellular unit Thus the terms *adaptation* and *training* crept into the bacteriologic literature

Although the experiment which would have disposed of the second hypothesis was initiated as early as 1928 (bacterial transformation) it was not analyzed completely until 1944 and its significance was not grasped until almost 1950

BACTERIAL VARIATION

The experimental approach to the analysis of bacterial variation was hindered by the failure to differentiate carefully between the variation of cultures as a whole and the variation of the individual organisms that made up the culture The appearance of an enzyme such as betagalactosidase in an *E coli* culture following the addition of the substrate lactose and the production by certain non lactose fermenting cultures of a few individuals capable of fermenting lactose are two quite different phenomena It is a culture of individuals of the latter class that exhibit the former phenomenon The remarkable success that has come to bacterial genetic analyses has in the main derived from careful separation of these two elements

The components necessary for a bacterial genetic analysis are cultures of individuals which are obtained by simple procedures from single organisms of the parental culture Because of the enormous numbers of individuals that can be grown in a short time and the general availability of procedures with a high degree of selectivity it is often possible to find unique and rare individuals For instance it is possible in 10^{10} organisms to find the one that is resistant to the drug streptomycin by plating large numbers of bacteria in the presence of the drug

With this conceptual approach Luria and Delbruck analyzed the mutation of *E coli* from phage sensitivity to phage resistance If the mutation was an adaptive response to phage infection then the sampling of one culture should give the same number of mutants as would the sampling of many independent cultures of the same kind On the other hand if the mutations occurred independently of the selective agent (the bacteriophage) as a random discrete process with a constant probability per bacterial generation then mutation would occur at different times during the growth of different cultures and give rise to a variable number of mutant descendants prior to the sampling The results of Luria and Delbruck indicated that the mutants occurred prior to and independent of the selective agent and that the only role of the selective agent was precisely what the term implies i e it selected the mutant forms

Another useful procedure leading to the same conclusion employed replica plating and an indirect selection of mutants (Lederberg and Lederberg) Bacteria were placed on a nutrient agar medium and allowed to grow to confluence If a mutation occurs during the growth of this culture the descendants of this mutant will be located at a fixed site on the agar surface By application of a piece of velveteen fabric about one third of the growth is removed and this is used to inoculate several other dishes containing a selective medium From the position of the mutants on the replica plates the position of the mutants on the master plate which never have been exposed to the selective agent can be inferred This area can be picked and replated and the process repeated Since only a small area of the master plate is picked relative to the total area of the plate this results in a considerable concentration of the mutant By repeating the procedure and plating smaller and smaller amounts of the area picked the size of the mutant clone grows larger and larger before exhaustion of the medium stops growth Ultimately a pure

clone of mutant organisms can be obtained in which neither these microorganisms nor any of their direct ancestors have been exposed to the selective agent

A procedure also is available for recovering mutants that have lost their capacity to synthesize particular substances The antibiotic penicillin only kills growing bacteria When a culture which contains mutants that require a particular amino acid for growth is inoculated into a medium which lacks this amino acid and contains penicillin the non mutant cells grow and are killed

Other ingenious procedures have been developed to study the nature of mutation and all have led to the same conclusion mutation is a spontaneous occurrence and independent of the nature of the selective agent This is not to say that mutation rates are independent of the organism s environment Quite a number of reagents will increase the mutation rate but they do so in a more or less nonspecific manner in that they affect many different genes

GENETIC TRANSFORMATION

The essential requirements for study of genetic recombination in any type of bacteria are (1) two potential parental lines of the organism which differ by at least one well-defined and readily recognizable property and (2) a means for selecting against at least one of these lines

The first experiment involving gene transfer in bacteria was probably that reported by Griffith in 1928 Mice are so susceptible to certain encapsulated (smooth or S) pneumococci that intraperitoneal injection of a few organisms will cause a fulminating infection which kills the mouse In contrast nonencapsulated (rough or R) pneumococci or heat inactivated pneumococci whether rough or smooth do not cause disease when injected into mice Griffith injected intraperitoneally a mixture of heat killed S pneumococci and viable R pneumococci The R pneumococci were derived from a different capsular type than the S The mice infected with this mixture died and living encapsulated pneumococci of the heat killed S type were recovered from them Both of the elements for a gene transfer experiment were present the differentially marked strains and the selective agent (in this instance the mouse) Although it was not recognized at this time gene transfer had occurred The resolution of the nature of this transforming system came in two stages In 1944, Avery McCarty and MacLeod showed that the material that caused the transformation of unencapsulated forms to encapsulated forms was deoxyribonucleic acid (DNA) The strictly genetic interpretation of this result awaited the demonstration that other pneumococcal properies such as drug resistance and M proteins (Hotchkiss) could be similarly transferred Physiologic functions as diverse as resistance to a drug and production of capsular polysaccharide and M proteins were controlled by a unique nucleic acid

The extraction of DNA from the culture of donor pneumococci and its application to recipient pneumococci result in the transformation of some of the recipient organisms The latter acquire a differentiating property of the donor The number of cells transformed is proportional to the amount of DNA applied to a saturation level of up to 10 per cent of all of the treated cells Cells which have been transformed for one property such as penicillin resistance are in general not transformed at the same time for another property such as capsulation Occasional instances of the simultaneous acquisition of two markers are known These results are interpreted as follows The genetic material of the pneumococcus is DNA On extraction it retains its genetic information and, on entering an appropriate host it displaces the homologous genetic material and functions as it did previously in its original host reproducing in synchrony with the cell and causing the expression of some new cellular property Since most of the genes are transformed independently of each other either they never coexisted in the same DNA structure or they were broken apart during the extraction The occasional instances of linked transformation are due to the proximate location on a DNA molecule of the genes controlling these properties

The larger organization of the genetic material in pneumococcus cannot be inferred from transformation As we shall see later

results obtained with other technics indicate that bacterial genetic material is organized in a single linear chromosomelike structure analogous to the organization found in higher forms

In addition to pneumococci transformation has been demonstrated in several other bacterial species These include members of *Hemophilus Bacillus Neisseria Streptococcus* and *Rhizobia* Surprisingly except in a very restricted sense transformation has not been demonstrated in *Enterobacteriaceae* probably a limitation in the reaction is the ability of the DNA macromolecule to penetrate bacteria In all instances of successful transformation there are extremely critical cultural conditions and other factors that are necessary for DNA uptake

The detailed molecular mechanism by which the transforming DNA is incorporated into the genome of the recipient bacterium is still unknown The current view is that the added DNA molecule or a part thereof is used directly by the bacterium and is incorporated into its genetic material for the building of its chromosomes

The work on transformation in bacteria and somewhat similar experiments with bacteriophage focused attention on DNA as genetic material They stimulated efforts to analyze the chemical composition and structure of this molecule

DNA is composed of 2 purine bases adenine and guanine and 2 pyrimidine bases thymine and cytosine the sugar deoxyribose and phosphate Chemical analysis of DNAs from diverse origin and of differing total compositions shows that the molar amount of adenine equals the molar amount of thymine and similarly the molar amounts of guanine and cytosine are equal For each mole of base there is one of sugar and phosphate As prepared by numerous procedures DNA is obviously a large polymer of these basic units

From x ray diffraction patterns of DNA fibers Watson and Crick were able to deduce a structure for DNA molecules This structure is a double helix with 2 intertwined chains of a sugar phosphate backbone the purine and the pyrimidine bases are placed between the chains much as the steps in a ladder The bases in one chain are hydrogen bonded to the bases in the other chain To achieve the required spacings it is necessary for the adenine residues to bond with the thymine residues and the guanine residues to bond with the cystosine residues thus accounting for the molar equivalence of these bases Such a structure is a complementary one such that the sequence of bases in one chain dictates the sequence in the other chain This characteristic immediately suggested a mechanism for DNA replication involving the separation of the chains and the addition of the complementary bases to the separated strands thus maintaining the chemical and therefore the genetic fidelity of the molecule Much evidence has been obtained which supports this mode of replication

The model also implies a mechanism for gene action It is assumed that genes control production of ribonucleic acid (RNA) of a certain type which is then used as a template for the synthesis of protein structures and enzymes RNA being very similar to DNA might be copied from DNA in a manner analogous to that of DNA replication Enzymes which use DNA as a template and synthesize DNA or RNA from nucleotide units have been found in many different organisms

TRANSDUCTION

Transduction was first demonstrated in *S typhimurium* by Zinder and Lederberg Like transformation this process involves the transfer from bacterium to bacterium of bits of genetic material but whereas this material is free in transformation it is carried by a bacterial virus in transduction

There are 2 classes of bacteriophage (bacterial viruses) those that can produce overt infection only (virulent phage) and those that can with varying frequency produce both an overt infection and a latent infection (temperate phage) In the latter instance following infection the phage disappears the bacteria do not produce progeny phage immediately but they now have as a permanent part of their phenotype the potential for the production of phage The nucleic acid of the phage which they carry in a prophage state is reproduced in synchrony

with the rest of the bacterial genetic material

Unlike their more virulent brethren, temperate phages do not kill all of the infected cells therefore alterations of bacterial properties can be seen Following infection with such temperate phages a variable proportion of the infected cells will respond either by lysing or by being latently infected (lysogenized) When the salmonella phage P22 is grown through a vegetative cycle on a well marked strain of *S typhimurium* and is applied to another differentially marked strain there is found among the lysogenic survivors of the infection an alteration in some cells of some of the differentiating properties The gross genetic manifestations of transduction are the same as those in transformation The number of cells transduced for any one property is proportional to the number of phage particles applied Cells transduced for one property are generally not transduced simultaneously for another There is a restriction in the amount of genetic material that can be transduced as the volume available in a phage particle amounts to about 1 per cent of the volume of the bacterial genome

A bacteriophage particle has an outer protein shell and an inner core of the nucleic acid which is its genetic material Apparently during the course of the growth of the phage protein coats are filled by pieces of bacterial nucleic acid instead of phage nucleic acid Such particles occur with fairly low frequency of the order of 1 in 1 million per genetic marker—and probably no more than 1 in 10 000 even if all the bits are summed These then are released with the rest of the phage progeny and on attachment to host bacteria enter them in the same way that phage nucleic acid does Instead of initiating the phage-controlled events this bacterial nucleic acid undergoes the same kind of genetic recombination process with the host genome that the free nucleic acid in transformation does Again instances of linkage are found Both transformation and transduction give rise to situations in which one can study to the exclusion of other genes those genes that are most closely linked together Because transduction was found in salmonella, a wide spectrum of nutritional markers was available for genetic analysis The low frequency of transduction was restrictive only in those instances in which the mutation rate of the gene in question was higher than the transduction frequency of about 10^{-6} *per infecting phage* particle—fortunately a not too frequent occurrence

The ability to concentrate the analysis on linked genes resulted in the revelation of a totally unsuspected feature of the spatial organization of genetic material in bacteria *It also allowed an approach to the funda*mental questions of the fine structure of the gene It was often found that the genes controlling the enzymes of a single biosynthetic pathway were linked We may cite as an instance the genes that control tryptophan biosynthesis There are 4 genes controlling *the synthesis of four enzymes which convert* anthranilic acid to tryptophan, and these are all linked In addition in this instance the order of the genes with respect to each other is the same as that of the reaction sequence Similar findings have been made for other biosynthetic systems This finding has been utilized by Jacob and Monod in developing the operon hypothesis wherein the time and the rate of synthesis of these enzymes are coordinated by their genetic linkage

Since independent mutations could be obtained which caused the loss of the same enzymatic function and therefore presumably were in the same gene it was possible to ask whether these had occurred at the same site in the gene or at different sites If genetic recombination could take place within a gene *even at a low frequency the* enormous resolution provided by the bacterial system could reveal it Phage was grown on one mutant which lacked the enzyme tryptophan synthetase and applied to another independently isolated mutant lacking the same enzyme and the number of the transductions to tryptophan independence was determined If transduction did not occur either the mutations were at the same site or a gene was not divisible by recombination *If transduction did occur the mutations* were at different sites and recombination within a gene could occur Transduction did occur and from the frequency of transduction in such one-by-one pairs there could be deduced a linear order of sites within a gene

which could undergo mutation and recombination The positioning of genes relative to each other is based on the idea common to all genetic recombinational analysis that is the higher the frequency of exchange the farther apart are the genes The same is assumed to be true for sites within a gene Considering the linear nature of the DNA structure this is not an unreasonable assumption Rigid proof of these notions was developed by Benzer in studies of the r gene in the bacteriophage T4

The genetic material that is transduced is not always integrated into the host genome These so-called abortive transductions occur about 10 times more frequently than do stable transductions They were discovered during studies on the transduction of motile flagellated bacteria to nonmotile nonflagellated strains The selection procedure employed a soft agar plate in which nonmotile forms grew but remained fixed at the site of inoculation whereas motile forms swarmed that is to say they migrated through the agar away from the inoculum site In addition to the swarms (stable transductions) there were trails of colonies in the agar proceeding away from the inoculum point These are explained as follows The gene for production of flagella enters a cell and causes the production of flagella For some unknown reason the gene is neither integrated into the genome of the host nor replicated independently of the genome thus it is passed to only one of the progeny cells when the bacterium divides During the period that the cell has flagella it can migrate on loss of the flagella due to segregation of the gene it ceases to migrate and initiates a colony at this point The daughter cell which receives the gene repeats the process hence the row of colonies

Abortive transductions can be found with other genetic markers also When the transduction is from nutritional dependence to independence there are many microcolonies in the agar in addition to the large colonies from the stable transductions These microcolonies are comparable with cells in a trail superimposed one on the other The nonreplicating gene during its passage through a number of cell generations caused the synthesis in each cell of sufficient enzyme to enable the cell to undergo a few further divisions The superposition of these cells forms the microcolony

A number of phages can cause transduction in a number of different bacteria such as *Bacillus Staphylococcus Pseudomonas Proteus* and *E coli* There are many phages which even though temperate do not transduce There is a property of phage growth—probably the way in which it disrupts the bacterial genome—that allows transduction

Transduction of the kind described in the preceding pages is general transduction in that it encompasses the entire bacterial genome with no preference for one gene over another Another variety of transduction also exists This is restricted transduction discovered in *E coli* and its temperate phage lambda When lambda grows in a vegetative cycle it does not cause the transduction of any known bacterial markers when applied to the appropriate host On the other hand when lambda lysogenizes its host and then is caused to undergo a vegetative cycle by induction with ultraviolet irradiation it transduces a few genes affecting the fermentation of galactose and these only The frequency of transduction is of the same order as that in general transduction about 1 per million The transduced cells are unstable Cells transduced from galactose nonfermentation to galactose fermentation continuously segregate galactose nonfermenting cells The frequency is about 1 per thousand per cell generation Apppar ently the transduced fragment is not integrated within the bacterial genome but does replicate almost in perfect synchrony with it Such cells are called heterogenetic They carry their original gene (endogenote) and the transduced fragment the exogenote They are in the older genetic terminology heterozygous but only for a small region of the genome These cells are also lysogenic and carry lambda When they in turn are induced with ultraviolet light they produce an extremely small yield of phage but a very high frequency of transducing particles The detailed analysis of this system has shown that a galactose transducing particle is a phage genome which has exchanged a portion of itself for the bacterium s galactose

with the rest of the bacterial genetic material

Unlike their more virulent brethren temperate phages do not kill all of the infected cells therefore alterations of bacterial properties can be seen Following infection with such temperate phages a variable proportion of the infected cells will respond either by lysing or by being latently infected (lysogenized) When the salmonella phage P22 is grown through a vegetative cycle on a well marked strain of *S typhimurium* and is applied to another differentially marked strain there is found among the lysogenic survivors of the infection an alteration in some cells of some of the differentiating properties The gross genetic manifestations of transduction are the same as those in transformation The number of cells transduced for any one property is proportional to the number of phage particles applied Cells transduced for one property are generally not transduced simultaneously for another There is a restriction in the amount of genetic material that can be transduced as the volume available in a phage particle amounts to about 1 per cent of the volume of the bacterial genome

A bacteriophage particle has an outer protein shell and an inner core of the nucleic acid which is its genetic material Apparently during the course of the growth of the phage protein coats are filled by pieces of bacterial nucleic acid instead of phage nucleic acid Such particles occur with fairly low frequency of the order of 1 in 1 million per genetic marker—and probably no more than 1 in 10 000 even if all the bits are summed These then are released with the rest of the phage progeny and on attachment to host bacteria enter them in the same way that phage nucleic acid does Instead of initiating the phage-controlled events this bacterial nucleic acid undergoes the same kind of genetic recombination process with the host genome that the free nucleic acid in transformation does Again instances of linkage are found Both transformation and transduction give rise to situations in which one can study to the exclusion of other genes those genes that are most closely linked together Because transduction was found in salmonella a wide spectrum of nutritional markers was available for genetic analysis The low frequency of transduction was restrictive only in those instances in which the mutation rate of the gene in question was higher than the transduction frequency of about 10^{-6} per infecting phage particle—fortunately a not too frequent occurrence

The ability to concentrate the analysis on linked genes resulted in the revelation of a totally unsuspected feature of the spatial organization of genetic material in bacteria It also allowed an approach to the fundamental questions of the fine structure of the gene It was often found that the genes controlling the enzymes of a single biosynthetic pathway were linked We may cite as an instance the genes that control tryptophan biosynthesis There are 4 genes controlling the synthesis of four enzymes which convert anthranilic acid to tryptophan and these are all linked In addition in this instance the order of the genes with respect to each other is the same as that of the reaction sequence Similar findings have been made for other biosynthetic systems This finding has been utilized by Jacob and Monod in developing the operon hypothesis wherein the time and the rate of synthesis of these enzymes are coordinated by their genetic linkage

Since independent mutations could be obtained which caused the loss of the same enzymatic function and therefore presumably were in the same gene it was possible to ask whether these had occurred at the same site in the gene or at different sites If genetic recombination could take place within a gene even at a low frequency the enormous resolution provided by the bacterial system could reveal it Phage was grown on one mutant which lacked the enzyme tryptophan synthetase and applied to another independently isolated mutant lacking the same enzyme and the number of the transductions to tryptophan independence was determined If transduction did not occur either the mutations were at the same site or a gene was not divisible by recombination If transduction did occur the mutations were at different sites and recombination within a gene could occur Transduction did occur and from the frequency of transduction in such one by-one pairs there could be deduced a linear order of sites within a gene

was simply to mix 2 lines of *E coli* that had acquired by mutation different nutritional requirements and to seek clones which had no nutritional requirements Thus on an unsupplemented minimal medium only recombinant colonies could grow The limiting frequency that could be measured was determined by the rate of spontaneous mutation of the parental culture to nutritional independence In addition to these selective marker mutations the strains differed by a number of other features which had no gross effect on the ability of the bacteria to grow (unselected markers) These features included fermentative ability drug and phage resistance and nutritional requirements which were supplied in the medium The analysis showed that recombinants were formed at a frequency of about 1 in 10^6 a value well above the frequency of spontaneous mutation in the unmixed parents When these recombinants were further tested for their unselected markers these were found to segregate as if there had been almost complete mixing of the 2 genomes The conclusions from this experiment were (1) bacteria are haploid i e they have only a single representative of each gene (2) they form a complete diploid heterozygote with a low frequency and (3) these zygotes undergo an immediate reduction back to the haploid state with a concurrent process of genetic recombination between the 2 genomes

The selected recombinants represent only one class of the total recombinants formed However because of the low frequency it was necessary to use the selective procedure to find some of them The phenomenon was not contingent on the nature of the selection This was demonstrated by using the same well marked parental cultures but with selection of different sets of markers Depending on the medium employed a given marker could be either selected or unselected The segregation of the unselected markers was not completely random that is it was not a case in which half of the progeny were similar to one parent and half to the other parent The precise pattern for any particular unselected marker depended on the markers that were used for selection of the recombinants This was interpreted as an indication of linkage between the selective and the nonselective markers In the diploid higher forms the genes are located on chromosomes and during the reductive meiotic cycle when the homologous chromosomes pair prior to separation they can undergo recombination with the interchange of parts The amount of interchange between 2 genes is taken as a measure of their physical distance apart on the linear chromosome The closer to one another the 2 genes are on the same chromosome the more rarely do they interchange An analogous mechanism was invoked for bacterial recombination and linkage maps were prepared If a marker had a great tendency to be derived from one of the parents it was presumed to be located near the selected marker of that parent

The original interpretation applied to bacterial mating was that any cell in the bacterial population had an equal probability of mating with any other bacterial cell there was no sexual differentiation From the work of Hayes Cavalli and the Lederbergs this picture was modified to give a simple but precise mating type differential It had been a fortuitous accident that the 2 lines of K 12 that had been used in the majority of crosses had the appropriate mating type

These 2 lines were derived from the original K 12 strain one being a methionine requiring (M—) mutant and the other a triple mutant isolated in sequential steps requiring threonine leucine and thiamine ($T—L—B_1—$) All of the mating stocks of *E coli* have been derived from either of these 2 lines by the addition or the subtraction of genetic markers

Hayes found that although the treatment of the M— line with either streptomycin or ultraviolet light did not prevent recombination treatment of the $T—L—B_1—$ with the same reagents did so Cavalli noted that crosses betwen stocks derived from the $TLB_1—$ line failed whereas crosses between stocks of the M— line still gave recombinants Thus there was a polarity in the mating and the lines were not equivalent in this regard Progeny of a cross could mate with either of the 2 lines In fact culture of the 2 lines together for brief periods followed by reisolation of the TLB_1 line on the basis of some differentiating marker made it possible for this derivative now to mate with

genes The phages are thus incomplete and are called lambda dg for lambda defective carrying galactose genes Such phage particles can grow only in the presence of a complete phage genome A galactose transduced cell contains a complete phage genome and a lambda dg It is the lambda dg that is lost in the unstable transductions

As yet only one other example of restricted transduction has been found that being in *E coli* where the phage ϕ80 carries the region concerned with tryptophan biosynthesis

In addition to acting as a carrier of genetic material from bacterium to bacterium bacteriophages also produce alterations of genetic properties of the host when they are carried as prophages The general property which is conferred on lysogenic organisms in addition to the ability to produce phage at a low, fixed frequency is immunity to superinfection by the phage that is carried

Besides these general alterations of bacterial properties certain bacteriophages produce other changes that are less well understood Perhaps the most profound of these is the conversion of non toxin producing *C diphtheriae* to toxin production by lysogenization with certain bacteriophages The toxin is released during the vegetative growth of the virus either following infection of sensitive cells or during the growth of the lysogenic cells In the latter instance only a small proportion of the cells in each cell generation produce phage and toxin

Phages are also responsible for the presence of certain of the well-characterized somatic antigens of salmonella species Lysogenization by P22 of group B salmonella results in the presence of somatic antigen 1 Those strains that have antigen 1 when isolated from nature can be shown almost invariably to contain P22 or a related phage This conversion is the result of the addition of a terminal glucose residue to the basic polysaccharide structure of the somatic antigen

Another well studied instance of conversion is in Group E of salmonella Strains with antigen 3 10 are modified to antigen 3 15 when they are lysogenized by E 15 phage When the 3 15 strains are further lysogenized by phage E 34, they become 3 15,34 Lysogenization of 3 10 strains by E 34 is without obvious effect The presence of 3 15 is required before E 34 can produce an observable effect Chemical analyses of these antigens reveal the detailed changes underlying these conversions The antigens 3 10 consist partly of a D galactosyl D mannose D rhamnose unit with an alpha linkage between the galactose and the mannose With the conversion to 3,15 this linkage is changed from alpha to beta Phage E 34 causes the addition of a terminal glucose residue to the galactose and apparently the galactose mannose linkage must be beta for this reaction to occur

Other instances of phage conversion are known to occur in other salmonella and in shigella Undoubtedly there are many as yet unresolved similar occurrences in bacteria Lysogenic bacteria are the rule rather than the exception

At present all attempts to develop a logical explanation for these conversions have failed A number of possibilities come to mind The conversions may be accidental in the sense that lysogenization causes an interference with some of the normal metabolic sequences of the cell resulting in these unexpected manifestations Alternatively either the phage may have evolved or the phage and the bacterium evolved from common gene segments the conversion representing the residual activity of this segment A corollary of the latter view is that conversion may represent an early evolutionary experiment in gene transfer Be that as it may it is obviously difficult to decide whether any particular bacterial property is caused by a phage or a bacterial gene In fact this question may be more semantic than real

BACTERIAL CONJUGATION

The mechanisms of genetic exchange that have been described previously are all very restricted in regard to the amount of genetic material that can be transferred at any one time Thus studies employing these mechanisms cannot yield information about the gross organization of bacterial genetic material In 1946 Lederberg and Tatum discovered bacterial conjugation in *E coli* strain K 12 and mutants derived from it The procedure

furthering the analysis The prophage lambda segregated in crosses as if it were linked to the galactose region of the *E coli* chromosome Recall that lambda was involved in the transduction of the galactose region specifically When a lysogenic Hfr was mated with nonlysogenic F— it was found that the prophage on entering the cytoplasm of a nonlysogenic bacterium underwent a process of induction (production of progeny phage) This then could give a precise measure of the zygotic events for it was not contingent on the integration of genetic material The entry of prophage into F— bacteria detected by subsequent phage production coincided in timing with the entrance of the galactose region

Garen and Skaar did a somewhat similar set of experiments with another Hfr (HfrC) but instead of blending they killed the Hfr parent with a virulent bacteriophage Their results also pointed to an orientation of transmission of genetic material but one with a different order than that obtained by Jacob and Wollman for Hfr H Crosses of lysogenic did not give zygotic induction and there was no transmission of the galactose marker

The Hfr have one other property which distinguishes them from F+ cells Mixture of F+ cells with F— cells rapidly converts the latter to F+ but mixture of Hfr with F— is without similar effect While the progeny of an F+ by F— cross are F+ the progeny of Hfr by F— crosses are primarily F— only those few progeny that receive the distal marker of the Hfr become Hfr

Jacob and Wollman developed the following concept of sexual differentiation in *E coli* F— cells lack an agent called F This agent in an F+ cell replicates in synchrony with but independently of the bacterial chromosome and is perhaps responsible for a change in the surface properties of bacteria such that they will unite with F— cells During such a union the F agent itself is transferred with a high frequency but the chromosome with a low frequency The transfer of the chromosome occurs following the same attachment of the F agent to the bacterial chromosome at any of a number of points perhaps at random giving rise to Hfr There can be isolated from F+ cells different Hfr These differ both in the nature of markers which they transmit and in the order of transmission of these markers Jacob and Wollman postulate that the chromosome in either an F— or a F+ cell is a closed ring structure The attachment of the F agent may convert this ring to a linear structure which transfers its chromosome in such a way as to have the F agent terminal

The attachment of the F agent to the bacterial chromosome receives further support from the phenomenon known as F duction Distal markers and the F agent in an Hfr by F— cross are transferred with a low frequency and very late after the mixing of the parental cultures If samples of mating mixtures are blended early after mixing and selection is made for some late entering marker a few recombinants are found These cells have the interesting property of transferring the F agent with a fairly high frequency and in addition to it, a few of the terminal markers of the Hfr which had been used in the original cross The F agent which had been attached terminally to the Hfr chromosome apparently dissociated from the bacterial chromosome carrying with it a bit of bacterial genome A number of different such agents called F′ have been isolated each carrying different bits of bacterial chromosome The genetic markers that are transferred by these contaminated F agents are rarely integrated into the recipient chromosome The situation is somewhat analogous to transduction of the galactose region by the lambda dg Cells carrying such F agents transfer their chromosome with a frequency intermediate between that of an Hfr and an F+ and the transfer has the same orientation as that of the Hfr from which the F agent has been derived The contaminated F agent has a preference for a particular site on the chromosome namely that for which it now has partial genetic homology These F agents are most useful in studying the genetic dominance relationships among bacterial genes as they give rise to persistent heterozygotes for the region involved rather than integrating into the bacterial chromosome

Several agents such as the F′ have been isolated in nature An *S typhosa* lac+ strain

strains with which it was previously incapable of mating. Since genetic recombination occurred at much lower frequencies, it was apparent that fertility itself was being transferred.

The definition of mating type is purely operational. Strains incapable of mating with each other are defined as F—. Strains that can mate with F— strains or with themselves are called F+. Fertility is controlled by the presence or the absence of an agent which is itself transferable in a mating interaction. Cell contact is required for F transfer, as no extraction procedure is successful. Thus conjugation can occur between pairs of bacteria differing primarily in mating type. When the segregation patterns for the unselected markers in these crosses were analyzed, it was found that the majority of the progeny had the markers of the F— parent. Mating type not only influenced the ability to undergo genetic recombination but also had a profound effect on the genetic composition of the progeny.

The interpretation given these results is that in a mating pair there is an unidirectional transfer of genetic material from the F+ strain to the F— strain. The transfer is never complete, thus accounting for the preponderance of markers of the F— parent. The sensitivity of the system itself to agents that kill F— cells but not to agents that kill F+ cells is thereby explained, for it is in reality from the F— cell that the recombinant progeny are derived. The inactivated F+ cells can still transfer some of their genetic material to the viable F— cell. The F agent allows for this genetic transfer.

The proof of this notion depended on a more detailed analysis of the process of mating. This was provided by the discovery of bacteria with a much higher frequency of mating and gene transfer. Two strains (called Hfr strains) were isolated, both derived from the M— line, which when mated with TLB_1— line gave frequencies of recombination of the order of 10 per cent of the parents. The frequency of recombination varied depending on the markers which were used to select the progeny. Apparently there was a gradient with regard to the frequency of transfer of different markers.

Jacob and Wollman studied the kinetics of mating of an Hfr (Hfr H) and F— cells in great detail. They mixed 2 stocks with multiple markers at high bacterial density and then they diluted the mixture at intervals and plated samples in order to determine the recombinant frequency. Other samples were diluted and agitated vigorously in a blendor and then plated for recombinants. Dilution and plating without blending prevented further coupling of bacteria, but those couples that had already formed could still transfer a considerable portion of their genome. However, blending of mated couples separated them at that time and prevented any further transfer of the Hfr genome.

Segregation of the unselected markers was studied in the 2 types of samples. The data were compiled in terms of the per cent of the recombinants that had any particular nonselective marker from the Hfr. For the unblended samples, this fraction remained constant and was independent of the time of sampling. If a marker appeared in 50 per cent of the progeny from the early samples, it had the same frequency in the later ones. However, for the blended samples this fraction increased as a function of the time of sampling, and each marker had its own time of appearance, characteristic rate of increase and maximum. Since the linkage relationship of the markers which was used was known from previous mating experiments, it was possible to analyze the results of the blendor experiment in terms of known linkages. This analysis indicated an oriented sequential passage of markers from the Hfr to the F— in the same linkage relation that had already been inferred.

The mating system described involves (1) combination of the cells of appropriate mating type by a surface interaction, (2) sequential passage of genetic material from Hfr to F—, and (3) its integration into the genetic material of the F—. The limitation in the analysis described above is that it is contingent on the integration of the genetic material. All of the data are obtained from the selected recombinant class, and the mechanism of gene interchange in this system is still incompletely understood and thus might bias the result.

A measurable property of the zygote itself proved to be a most useful tool for

furthering the analysis The prophage lambda segregated in crosses as if it were linked to the galactose region of the *E coli* chromosome Recall that lambda was involved in the transduction of the galactose region specifically When a lysogenic Hfr was mated with nonlysogenic F— it was found that the prophage on entering the cytoplasm of a nonlysogenic bacterium underwent a process of induction (production of progeny phage) This then could give a precise measure of the zygotic events for it was not contingent on the integration of genetic material The entry of prophage into F— bacteria detected by subsequent phage production coincided in timing with the entrance of the galactose region

Garen and Skaar did a somewhat similar set of experiments with another Hfr (HfrC) but instead of blending they killed the Hfr parent with a virulent bacteriophage Their results also pointed to an orientation of transmission of genetic material but one with a different order than that obtained by Jacob and Wollman for Hfr H Crosses of lysogenic did not give zygotic induction and there was no transmission of the galactose marker

The Hfr have one other property which distinguishes them from F+ cells Mixture of F+ cells with F— cells rapidly converts the latter to F+ but mixture of Hfr with F— is without similar effect While the progeny of an F+ by F— cross are F+ the progeny of Hfr by F— crosses are primarily F— only those few progeny that receive the distal marker of the Hfr become Hfr

Jacob and Wollman developed the following concept of sexual differentiation in *E coli* F— cells lack an agent called F This agent in an F+ cell replicates in synchrony with but independently of the bacterial *chromosome and is perhaps responsible* for a change in the surface properties of bacteria such that they will unite with F— cells During such a union the F agent itself is transferred with a high frequency but *the chromosome with a low frequency The* transfer of the chromosome occurs following the same attachment of the F agent to the bacterial chromosome at any of a number of points perhaps at random giving rise to *Hfr There can be isolated from F+ cells* different Hfr These differ both in the nature of markers which they transmit and in the order of transmission of these markers Jacob and Wollman postulate that the chromosome in either an F— or a F+ cell is a closed ring structure The attachment of the F agent may convert this ring to a linear structure which transfers its chromosome in such a way as to have the F agent terminal

The attachment of the F agent to the bacterial chromosome receives further support from the phenomenon known as F duction Distal markers and the F agent in an Hfr by F— cross are transferred with a low frequency and very late after the mixing of the parental cultures If samples of mating mixtures are blended early after mixing and selection is made for some late entering marker a few recombinants are found These cells have the interesting property of transferring the F agent with a fairly high frequency and in addition to it a few of the terminal markers of the Hfr which had been used in the original cross The F agent which had been attached terminally to the Hfr chromosome apparently dissociated from the bacterial chromosome carrying with it a bit of bacterial genome A number of different such agents called F have been isolated each carrying different bits of bacterial chromosome The genetic markers that are transferred by these contaminated F agents are rarely integrated into the recipient chromosome The situation is somewhat analogous to transduction of the galactose region by the lambda dg Cells carrying *such F agents transfer their chromosome* with a frequency intermediate between that of an Hfr and an F+ and the transfer has the same orientation as that of the Hfr from which the F agent has been derived *The contaminated F agent has a preference* for a particular site on the chromosome namely that for which it now has partial genetic homology These F agents are most useful in studying the genetic dominance *relationships among bacterial genes* as they give rise to persistent heterozygotes for the region involved rather than integrating into the bacterial chromosome

Several agents such as the F have been isolated in nature An *S typhosa* lac+ strain

TABLE 1 MATING TYPES OF *E coli*

was found to transfer the lac character to many different strains including some species of *Proteus* and *Serratia*

Jacob and Wollman have given the name episomes to those elements which have genetic function and can exist in both an autonomous and an integrated state Among these are the temperate phages and the F agents with their varying degrees of contamination

The factors which control the production of colicins also behave as episomes Colicins are antibioticlike agents produced by certain bacterial strains Unlike the other antibiotics they have a limited host range usually only a few species or strains of bacteria are susceptible Fredericq has shown that the capacity to produce colicine can be transferred from strain to strain in a matinglike process However when studied in *E coli* this agent was sometimes transferred independently from the chromosome and at other times as an integrated entity Stocker and Ozeki have shown that the presence of certain colicin agents causes gene transfer in addition to the transfer of the colicin property They mimic the F agent in this respect

A most remarkable episome was discovered in Japan by Akiba About 1953 it was noted that many epidemics of shigellosis were being caused by organisms which exhibited multiple drug resistance The organisms were resistant to streptomycin tetracyline chloroamphenicol and sulfonamides Some patients excreted both sensitive and multiple resistant strains This drug resistance could be transferred in mixed culture from strain to strain through the *Enterobacteriaceae* and to *Serratia* and *Vibrio* strains The agent has been called RTF (resistance transferring factor) Its transfer seems to be quite independent of the F state of the bacteria in fact when RTF and F coexist in the same strain the F induced properties are usually repressed Some of the F— strains carrying RTF can also transfer their chromosomal markers

As with the other autonomous factors the RTF are slowly lost spontaneously during the course of repeated cell culture Hirota has shown that *E coli* can be repeatedly cured of the autonomous F factors by growth in the presence of acridine dyes RTF strains can be similarly cured The acridines apparently affect only the nonintegrated forms as F is not lost from Hfr bacteria when they are similarly treated

The mating types of *E coli* and some of their properties are shown in Table 1

DNA BACTERIAL TAXONOMY AND EVOLUTION

The picture that has emerged of the genetic material of bacteria is a composite based on all of the genetic systems that have been described There is in a bacterium a chromosomelike structure which is composed primarily of DNA There is some evidence both genetic and cytologic that the structure is a closed ring in *E coli* Along the length of the structure in serial fashion are located the genes that control the synthesis of the components of the bacterium The amount of DNA in an *E coli* chromosome is estimated to be 5×10^9 daltons (units of molecular weight) However it is not certain whether the structure represents a single giant molecule of DNA or perhaps smaller units tied together in noncovalent linkages Thus DNA such as that used in transforming systems either is broken in extraction into random pieces or is separated into the discrete molecules There is evidence from transformation that the individual markers reside on definitely characterizable molecules for example different markers have different denaturing temperatures on heating There is also some evidence from transduction that the pieces effecting transmission of any particular marker have fixed not random ends Both results indicate a prepackaging of DNA in definite bits Be that as it may the genes are units of DNA containing on the order of 500 to 1 000 nucleotide pairs The specific sequence of these nucleotide pairs is assumed to be di

rectly related to the amino acid sequence of the secondary gene products the protein structures and enzymes Mutation occurs by the alteration of one or more of the nucleotide pairs within the gene which thereby changes the structure of an enzyme either decreasing or increasing its functional ability Since the gene is fairly large it is apparent that mutation to loss of function is more likely than that to gain of function It is also probable that some base changes may be insignificant for although they cause a change in the structure of an enzyme this change might not alter its active center Such ineffective mutations could accumulate throughout a gene and provide a means for gene evolution

Analysis of the base ratio of the DNA from different bacteria shows that they differ widely in composition, from GC 30 per cent for clostridia to GC 70 per cent for Sarcina (mole % guanine + cytosine/mole % guanine + cytosine + adenine + thymine) From the previous considerations it is apparent that for organisms to be related they should have similar base compositions For example organisms such as coliform salmonella and shigella strains all have about 50 per cent GC While different base ratios can be an indicator of nonrelationship similar base ratios do not prove relationship Many neisseria strains have the same base ratio as organisms of the coliform group Within groups of organisms with the same base ratio more detailed physicochemical analyses of DNA and its sequence can be used as indicators of homologies and hence relationships While the methodology of bacterial genetics makes available some new and scientifically more valid approaches to problems of bacterial taxonomy it seems quite unlikely that these will significantly disturb the current system of classification in the near future

All of the processes of genetic exchange that have been discovered thus far in bacteria involve the partial transfer of genetic material Thus they leave the recipient bacterium intact except for a small bloc of genes In haploid organisms such as bacteria one might imagine that there would be such a degree of homeostasis that the introduction of a large bloc of new genes would produce considerable metabolic unbalance In diploid forms such effects can be cushioned by the homologous chromosome Therefore the systems of exchange offer the organisms the choice of accepting small and perhaps useful bits of genetic material without disturbing their essential integrity There is no doubt that these processes could occur in nature However there is little evidence that they do occur It has been shown that with transformable systems nucleic acid often accumulates during bacterial growth In at least one instance timing of release of nucleic acid by the culture has been demonstrated to coincide with the time of the cells maximum sensitivity to the uptake of nucleic acid Bacteriophages are numerous and of course always are to be found in the same ecologic niche as their hosts so that transductions and conversions could occur The most promiscuous of the sexual like processes F duction has been shown in the laboratory to cross species lines readily Since strains isolated from nature harbor such elements F duction might be quite prevalent We may cite as examples the shigella strains isolated from epidemics in Japan in which multiple drug resistance was shown subsequently to be due to a transferable factor

That genetic exchange plays an important and continuous role in nature cannot be proved or disproved at this time For evolutionary purposes a few instances of gene interchange suffice However it is most obvious that free gene interchange does not occur for if it did we should not expect to encounter the variety of organisms that currently exist The problem of the genetic isolation of microorganisms is in most senses no more complicated than that of the genetic isolation of higher forms Often simple separation due to particular favored ecologic niches separate organisms which are quite capable of gene interchange In time they might evolve in such a way as to prevent interchange even on cohabitation Each of the mechanisms of gene exchange that has been described has obvious limitations in its range and efficiency Transformation reactions involve the uptake of a large linear and highly negatively charged macromolecule For uptake to occur the environmental conditions the strain of bacteria and the stage

of bacterial growth must be critically selected The very high frequencies of transformation that can be achieved in the laboratory require extreme attention to these details Transduction processes and others which involve bacteriophages are restricted to the host range of the phage itself Phages show an exquisite degree of specificity in regard to the organisms to which they can attach For example transducing salmonella phage P22 attaches only to organisms which have somatic antigen 12 Similar restrictions exist for other phages and hence restrict their genetic potential Mating reactions involve the conjugation of 2 bacterial cells and require the presence of particular surface bacterial structures for the building of a fusion bridge In addition to their ability to promote transfer per se transfer factors must also alter the surface of their host bacteria in such a way as to make possible such cellular fusions

Genetic exchange can also be restricted by factors unrelated to the penetration stage While the molecular mechanism of gene recombination is still obscure it is nevertheless apparent that if replacement of material is to occur the exogenote and the endogenote must in some way recognize each other They must have some degree of molecular homology By mating analysis it can be shown that the general order of the genes controlling specific functions is the same in *E coli* and some salmonella Hybrids of *E coli* and salmonella strains have been prepared which have known portions of their genome derived from the salmonella and known portions from the *E coli* By appropriate choice of the hybrid strains can be prepared which will grow the transducing phage P22 Transduction of coli genes by coli genes and transduction of salmonella genes by salmonella genes occurs readily However transduction of coli genes with salmonella genes and salmonella genes with coli genes either fails or occurs with a much reduced frequency In matings in which extensive regions of genetic material are involved sufficient homology can be found for genetic recombination In transduction which involves only small regions there is apparently insufficient homology for the pieces to recognize each other Similar results have been obtained with transformation within various strains of *Hemophilus Bacillus* and *Streptococcus* In the latter instances the gross structure of the genetic material is as yet unknown

Bacterial Metabolism*

In this brief review of bacterial physiology and metabolism no attempt will be made to cover all of the varied patterns found in bacteria and fungi Rather the emphasis will be placed on those aspects which are peculiar to these microorganisms and tend to set them apart from other forms Through such an understanding of differences between microorganisms and their hosts we can hope to develop a more rational approach to chemotherapy and to other means for the control of bacterial infection However we must also understand the ways in which bacteria differ in their metabolic patterns from each other since these differences frequently provide the means for distinguishing between closely related species Together with morphologic and immunologic criteria metabolic characteristics provide a basis for the classification of bacteria Furthermore the presence or the absence of a metabolic trait frequently may be correlated with the presence or the absence of pathogenicity

* Abbreviations used in this chapter include the following
AMP—adenosine monophosphate
ATP—adenosine triphosphate
CDP—cytidine diphosphate
DNA—deoxyribonucleic acid
DNP—dinitrophenol
DPN—diphosphopyridine nucleotide
DPNH—reduced diphosphopyridine nucleotide
GTP—guanosine triphosphate
IDP—inosine diphosphate
ITP—inosine triphosphate
RNA—ribonucleic acid
TPN—triphosphopyridine nucleotide
TPNH—reduced triphosphopyridine nucleotide
UDP—uridine diphosphate

GROWTH

Methods of Measurement

In any population of cells growth may result either from an increase in the mass of the individual cells or from an increase in the cell number Under ideal conditions the average cell size or mass is very constant and a determination of one represents a determination of the other Thus under true physiologic conditions procedures which measure either the total number of cells or the total amount of cell material will provide suitable indices of growth The total number of cells may be counted directly using a counting chamber particularly with dark field illumination More frequently the number of viable cells in the population is determined by plating the cells on suitable growth media and counting the colonies which arise from the individual cells The latter procedure yields the viable count since it does not include cells which are dead and fail to give rise to colonies Growth may also be determined by measuring the bacterial density in one of several ways The basic reference is provided by measurement of the dry weight which can be related to nitrogen content metabolic activity packed cell volume or most common of all turbidity or absorbancy of light (optical density) at a prescribed wave length

The data obtained ln any of these pro cedures may be expressed by plotting the appropriate parameter against time When cells which have not been growing actively (usually referred to as resting cells) are placed in a medium which can support growth the growth curve passes through several phases shown schematically in Figure 1 *In the first phase called the lag phase* there is usually very little increase in cell number although there may be some increase in cell mass This is followed by the loga rithmic or exponential phase in which the cells are increasing in mass and dividing at an exponential rate Ultimatelj if the cells are not transferred to *fresh medium they* will pass into the resting or stationary phase during which there is little further increase in mass or cell number In many cases this *is followed* by a decrease in the number of cells They will pass into the death phase or phase of decline in which there may be a breakdown of cells or lysis and a liberation of their contents into the medium

Since bacteria divide by a process called binary fission their number (B) will increase by powers of two,

$$B = b\,2^{n}$$

where b is the initial number of cells and n the number of cell divisions or generations This equation is an expression of the growth rate during the exponential phase For the time interval $t\ t_0$ (in hours) this may be expressed as

$$B = b\,2^{(t\ t)}$$

where r is the growth rate in divisions per hour, therefore $n = r(t\ t_0)$ This equation can be converted to the logarithmic form

$$\log_{.} B - \log\ b = r(t\ t\ )$$

The gcneration time g is the reciprocal of *the growth rate r and is therefore equal to*

$$g = \frac{t\ t}{(\log\ B - \log\ b)}$$

Often it may be more convenient to express this in ordinary logarithms

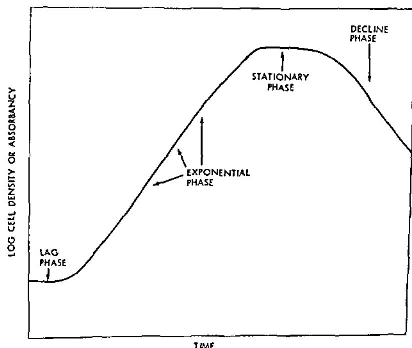

FIG 1 Bacterial density curve showing phases of growth

$$g = \frac{t\ t}{0\ 301(\log_{10} B - \log_{10} b)}$$

The generation time can be read from a plot of log B versus t If the data are plotted in ordinary logarithms (base 10) then the time required for a change of 0 301 represents the generation or doubling time

FACTORS AFFECTING THE GROWTH RATE

During the lag phase the failure of the cells to divide may reflect the time required to fill their metabolic pools and synthesize the appropriate enzymes and coenzymes During the exponential phase the growth rate may vary according to the composition of the medium the temperature and the rate of aeration With aerobic cells vigorous stirring and aeration frequently with pure oxygen may be required for maximum growth rates The nature of the substrate and the composition of the medium will affect growth In general cells grown on enriched medium will divide more frequently than cells growing on a minimal medium Reasons for this will be discussed in a later section

The effect of temperature on growth rate may be quite complex In the ordinary temperature range the growth rate usually will increase with temperature much as do physiologic processes in general At higher temperatures growth may slow down or cease Optimum temperature for growth is usually a reflection of the normal environment of the organism Thus pathogenic bacteria usually will grow best at 37 C Yeasts and fungi for the most part prefer lower temperatures and are usually cultivated at room temperature or 30 C Bacterial cells vary enormously in their response to elevated temperatures and in general pathogenic species are inhibited in their growth or even killed at temperatures above 45 C Occasionally mutations are encountered which result in changes in thermostability or thermolability In nature we find organisms growing at temperatures approaching the boiling point of water These are generally referred to as thermophils and will grow at temperatures at which other organisms are unable to grow The biochemical basis for differences in response to temperature remains obscure

Cells entering the stationary phase of growth may do so because of changes in the environment such as a fall in pH exhaustion of some essential component from the

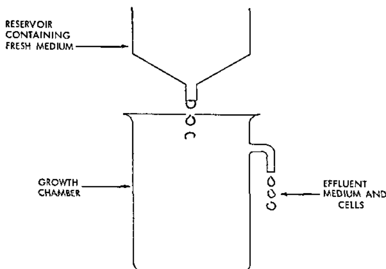

FIG 2 Diagrammatic representation of chemostat for controlled exponential growth of cells

medium, or accumulation of a toxic metabolite Aerobic organisms may cease to grow when they are crowded simply because it is impossible to provide enough oxygen even by vigorous aeration to maintain further growth However if such changes in the medium are avoided the cells may be maintained in the exponential phase indefinitely An example of this is provided by the use of the chemostat This is a device in which fresh medium is continually added to the cell suspension at the same rate at which medium and cells are removed from the system Under these conditions the number of cells will increase at first until one of the components of the growth medium becomes limiting then the cells will grow at a rate which is determined by the rate of addition of this component This apparatus is represented diagrammatically in Figure 2 The chemostat is of value in studies where it is desired to have a predetermined generation time and yet maintain exponential growth conditions It is also used to determine effects of added metabolites since in the chemostat the limiting metabolite generally exists at very low concentration

Synchronous Growth

Under appropriate conditions a population of cells will divide synchronously yielding discontinuous growth curves based on viable count data Cells may be brought into synchronous growth by allowing an essential component of the medium to be depleted and then adding this component or by abrupt changes in temperature Perhaps the most physiologic method for bringing cells into synchronous growth is to use an inoculum of young cells which can be obtained by selective filtration The smallest cells which pass through appropriate selective filters will be growing cells which have just undergone cell division for a few generations these will continue to grow and divide synchronously Such cell populations are useful in the study of control mechanisms which regulate cell growth and division

Nutritional Requirements for the Growth of Bacteria

A suitable environment which will support the growth of a microorganism must contain sources of all of the elements which go to make up the bacterial cell The principle elements required are carbon nitrogen phosphorus, sulfur oxygen and hydrogen In addition most cells require significant quantities of a number of cations including potassium manganese magnesium and iron as well as calcium zinc and copper Trace quantities of a number of other cations are found in bacterial cells but these are usually introduced as contaminants of other components of the medium and it is difficult to demonstrate a definitive need for these compounds The principle anions required for growth are chloride sulfate and phosphate Some cells are unable to utilize sulfate and sulfur and for these sulfur must be provided in the form of organic or inorganic sulfides Finally all cells in order to grow must have available a suitable source of energy Often this is furnished by the same compound which provides the source of carbon

Although bacteria are similar in their basic composition they differ in synthetic capacity Many species are able to survive on purely inorganic media and to derive carbon from carbon dioxide These are designated *lithotrophs* These organisms must use either light or chemical energy to accomplish the reduction of carbon dioxide by the elements of water The *photosynthetic lithotrophs* gain their energy from light by the process of photosynthesis the *chemosynthetic lithotrophs* obtain energy by the oxidation of inorganic substances such as ferrous iron sulfide elemental sulfur or thiosulfate ammonia nitrite, or even hydrogen

Photosynthesis in bacteria is unlike photosynthesis in higher plants in one important respect it is never accompanied by the production of oxygen Photosynthetic bacteria generally thrive only in an anaerobic environment which also contains a suitable hydrogen donor or reducing agent This difference between photosynthetic bacteria and green plants is illustrated best by a consideration of the equations of photosynthesis In green plants the process is represented by the following equations in which $h\nu$ represents the energy in a quantum of light (H) and (OH) represent reducing and oxidizing products derived from water and (CH_2O)

represents the ultimate product carbohydrate

$$(1)\ 4\,H_2O + 4\,h\nu \longrightarrow 4\,(H) + 4\,(OH)$$

$$(2)\ 4\,(H) + CO_2 \longrightarrow (CH_2O) + H_2O$$

$$(3)\ 4\,(OH) \longrightarrow 2\,H_2O + O_2$$

$$(\text{Sum})\ H_2O + CO_2 \xrightarrow{h\nu} (CH_2O) + O_2$$

In photosynthetic bacteria the reaction represented by equation 3 (the production of oxygen) does not occur this reaction is replaced by

$$(3a)\ 4\,(OH) + 2H_2A \longrightarrow 4\,H_2O + 2A$$

and the sum is

$$(\text{sum})\ CO_2 + 2\,H_2A \xrightarrow{h\nu} (CH_2O) + 2A$$

H_2A represents a hydrogen donor or reducing agent this may be hydrogen sulfide or another inorganic reducing agent or in some species an organic reducing agent such as malic acid In the photosynthetic sulfur bacteria large quantities of free sulfur accumulate The nutritional requirements of photosynthetic organisms will be determined by the nature of the reducing agent which they can employ The situation is very similar for chemosynthetic organisms

In contrast with the lithotrophs the *organotrophs* (or *heterotrophs*) require as a source of energy an organic nutrient which they can oxidize or ferment The photosynthetic organisms which require organic reducing compounds are also classified as organotrophs more specifically they are called *photo-organotrophs* or *photoheterotrophs* In addition bacteria may require a variety of organic growth factors including many of the vitamins which are required by man and often in addition certain amino acids purines pyrimidines and other substances Many species may have very complex growth requirements and some pathogens cannot be cultivated on defined media Microorganisms which require specific growth factors have been widely employed as sensitive microbiologic assay systems since under defined conditions the amount of growth is directly proportional to the quantity of growth factor provided Before the advent of chromatographic methods microbiologic assays were common for amino acids purines and pyrimidines It was with the aid of such methods that it was established that deoxyribonucleic acids contain equivalent amounts of adenine and thymine and of guanine and cytosine

In recent years microbiologic assays have been used for the isolation of new growth factors some of which have subsequently been found to be important in the nutrition of higher animals Often bacteria require more complex forms of the vitamins than are needed in animal nutrition For example *Hemophilus influenzae* will not grow on nicotinic acid or nicotinamide but requires the intact nicotinamide riboside linkage and will grow best on DPN or TPN Often these requirements for more complex forms of the vitamin have provided clues to the nature of the coenzyme form An example of this is the structure of coenzyme A which contains pantothenic acid The vitamin pantothenic acid was first shown to promote yeast growth and later to be required for many bacterial species The 2 components of pantothenic acid β alanine and pantoic acid will replace pantothenic acid itself in some cases since some species cannot synthesize the β alanine portion while others cannot synthesize pantoic acid *Lactobacillus bulgaricus* on the other hand requires a conjugated form of pantothenic acid pantotheine This substance at one time called the lactobacillus factor can be derived from coenzyme A by the action of phosphatase and its identification was of great importance in the elucidation of the structure of coenzyme A The arrangement of these components in the coenzyme A molecule is shown in Figure 3

Bacterial vitamins include many of the vitamin B group such as thiamine riboflavin pyridoxal and nicotinic acid In addition bacteria may also require p amino benzoic acid folic acid hemin and vitamin K Sterol vitamins are unknown and the presence of sterols in bacteria has not been substantiated although certain yeasts may contain large quantities Nor has any requirement for ascorbic acid been demonstrated in bacteria Carotenes participate in bacterial photosynthesis

Origin of Nutritional Requirements

It is of interest to consider the possible evolution of these growth requirements and

medium or accumulation of a toxic metabolite Aerobic organisms may cease to grow when they are crowded simply because it is impossible to provide enough oxygen, even by vigorous aeration to maintain further growth However if such changes in the medium are avoided the cells may be maintained in the exponential phase indefinitely An example of this is provided by the use of the chemostat This is a device in which fresh medium is continually added to the cell suspension at the same rate at which medium and cells are removed from the system Under these conditions the number of cells will increase at first until one of the components of the growth medium becomes limiting then the cells will grow at a rate which is determined by the rate of addition of this component This apparatus is represented diagrammatically in Figure 2 The chemostat is of value in studies where it is desired to have a predetermined generation time and yet maintain exponential growth conditions It is also used to determine effects of added metabolites since in the chemostat the limiting metabolite generally exists at very low concentration

Synchronous Growth

Under appropriate conditions a population of cells will divide synchronously yielding discontinuous growth curves based on viable count data Cells may be brought into synchronous growth by allowing an essential component of the medium to be depleted and then adding this component or by abrupt changes in temperature Perhaps the most physiologic method for bringing cells into synchronous growth is to use an inoculum of young cells which can be obtained by selective filtration The smallest cells which pass through appropriate selective filters will be growing cells which have just undergone cell division for a few generations these will continue to grow and divide synchronously Such cell populations are useful in the study of control mechanisms which regulate cell growth and division

Nutritional Requirements for the Growth of Bacteria

A suitable environment which will support the growth of a microorganism must contain sources of all of the elements which go to make up the bacterial cell The principle elements required are carbon nitrogen phosphorus sulfur, oxygen and hydrogen In addition most cells require significant quantities of a number of cations including potassium manganese magnesium and iron as well as calcium zinc and copper Trace quantities of a number of other cations are found in bacterial cells but these are usually introduced as contaminants of other components of the medium and it is difficult to demonstrate a definitive need for these compounds The principle anions required for growth are chloride sulfate and phosphate Some cells are unable to utilize sulfate and sulfur and, for these sulfur must be provided in the form of organic or inorganic sulfides Finally all cells in order to grow, must have available a suitable source of energy Often this is furnished by the same compound which provides the source of carbon

Although bacteria are similar in their basic composition they differ in synthetic capacity Many species are able to survive on purely inorganic media and to derive carbon from carbon dioxide These are designated *lithotrophs* These organisms must use either light or chemical energy to accomplish the reduction of carbon dioxide by the elements of water The *photosynthetic lithotrophs* gain their energy from light by the process of photosynthesis the *chemosynthetic lithotrophs* obtain energy by the oxidation of inorganic substances such as ferrous iron sulfide elemental sulfur or thiosulfate ammonia nitrite or even hydrogen

Photosynthesis in bacteria is unlike photosynthesis in higher plants in one important respect it is never accompanied by the production of oxygen Photosynthetic bacteria generally thrive only in an anaerobic environment which also contains a suitable hydrogen donor or reducing agent This difference between photosynthetic bacteria and green plants is illustrated best by a consideration of the equations of photosynthesis In green plants the process is represented by the following equations in which *hν* represents the energy in a quantum of light (H) and (OH) represent reducing and oxidizing products derived from water, and (CH O)

for energy *Aerobes* depend on respiration and require oxygen these must be grown with shaking or aeration *Faculative anaerobes* can derive energy from fermentation and will grow in the absence of oxygen but will survive and often thrive in the presence of air *Obligate anaerobes* on the other hand can be grown successfully only in the complete absence of oxygen and may be killed if even traces of air are present

Electron Transport in Aerobic Microorganisms

Aerobic organisms derive their energy from oxidations which resemble those found in higher animals This process known as *respiration* involves the oxidation of the substrate by molecular oxygen through the intervention of the electron transport mechanism (Fig 4) The bacterial cytochromes which catalyze the terminal steps in the chain of electron transport (Fig 5) resemble those found in mammalian cells and in yeast and studies of absorption spectra of bacteria have disclosed the presence of cytochromes of the a a_3 b c and c_1 types However bacterial cytochromes frequently differ from mammalian or yeast cytochromes in the precise location of their absorption bands as well as in their catalytic properties In general cytochrome of the c type isolated from bacteria will not react with reduced pyridine nucleotide in the presence of mammalian cytochrome reductase and the oxidation of the reduced form is not catalyzed by mammalian cytochrome oxidase (cytochromes a + a_3) Some species of microorganisms are completely lacking in cytochrome c yet possess an active electron transport chain Cytochromes of the c type also function in bacterial photosynthesis and in nitrogen fixation

Cytochromes of the b type are frequently encountered in bacteria and may act as components of the electron transport mechanism as is shown in Figure 5 In a few cases they have a distinctly different function Lactic dehydrogenase isolated from yeast has been characterized as a cytochrome b like compound (designated cytochrome b) and a cytochrome of this type has also been im

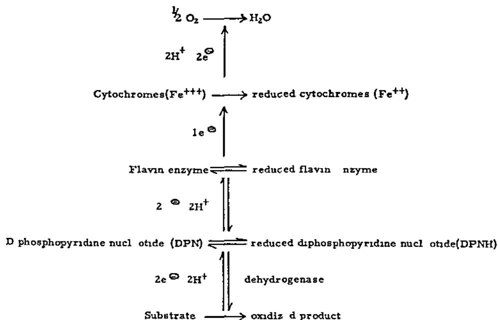

Fig 4 Schematic representation of the path of electrons and protons in respiration

particularly to inquire as to the evolutionary sequence of appearance of lithotrophs and organotrophs According to an older theory primitive organisms possessed very simple growth or nutritional requirements According to this view heterotrophic forms developed through a gradual loss of synthetic power by a type of functional degeneration Thus mutants with specific deletions would be forced to satisfy their requirements from the surrounding medium This theory was attractive because such changes (loss of synthetic capacity) were commonly observed in spontaneous or induced mutants Recently however there has been a tendency to favor the opposite point of view namely that the most primitive organisms were organotrophs which arose in primordial seas containing all of the requirements of the cell These organisms would be expected to possess a very limited synthetic capacity As essential nutrients were depleted from the environment mutants were selected which had developed the capacity to synthesize the missing precursors The attractive feature of this second theory is that it avoids the requirement for a sudden appearance of a living cell having a very complex metabolic machinery capable of synthesizing all of the essential components of the cell This hypothesis is also in accord with current concepts as to the composition of the primordial hydrosphere

Changes in Cell Composition With Changes in Growth Rate

It has been mentioned that the growth rate (or reciprocal of the generation time) is a function of the composition of the medium and that cells generally will grow more rapidly in an enriched medium where they are not required to synthesize all of the amino acids purines pyrimidines and other cell components Such rapidly growing cells also show increases in average cell size and in the number of nuclei per cell They are relatively rich in their complement of RNA DNA and protein although these increases are not proportionate Thus bacteria isolated from enriched medium contain relatively more RNA and protein than DNA as compared with cells growing in minimal medium This effect is seen most strikingly when cells are transferred from minimal to enriched medium the quantity of DNA and total mass per cell may increase by approximately 2 fold while the content of RNA and protein may increase as much as 3 fold These changes follow a particular time sequence When cells growing exponentially in a minimal salt medium are transferred to nutrient broth several generations may pass without any notable change in the rate of cell division The first change to be observed is an immediate increase in the rate of synthesis of RNA This is followed later by a change in the rate of synthesis of protein and finally of DNA Ultimately after about 60 minutes have elapsed there will also be observed an increase in the rate of cell division These changes may be related to increases in specific types of RNA and to cellular control mechanisms (see below)

ENERGY METABOLISM

Bacteria fall into several groups according to their means of satisfying their requirement

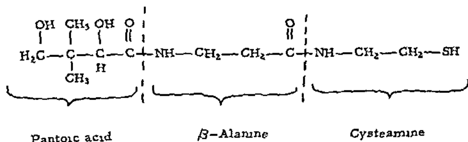

Fig 3 Structure of pantotheine and its components In Coenzyme A adenosine 3 phosphate is attached to the terminal OH group of pantoic acid by a 5 pyrophosphate bridge

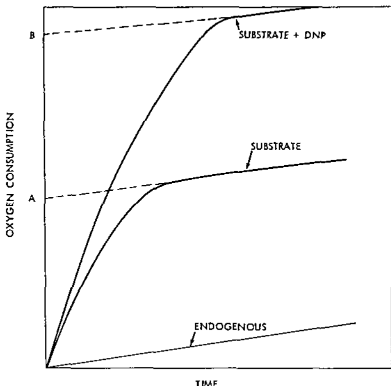

FIG 6 Schematic representation of oxidative assimilation and its uncoupling by dinitrophenol A and B represent the net oxygen uptake due to the substrate in the absence and the *presence of dinitrophenol* respectively

cultivated in the presence of oxygen if agents are added to maintain a low oxidation reduction potential Examples of such agents are ascorbic acid and cysteine both of which will facilitate growth of obligate anaerobes in the presence of oxygen It is noteworthy that these compounds will reduce oxygen to hydrogen peroxide and therefore tend to increase rather than decrease the concentration of this substance

A better hypothesis to account for the sensitivity of obligate anaerobes to oxygen is based on the sensitivity to oxidation of the proteins found in anaerobes Enzyme preparations from clostridia must be protected from oxygen by maintaining anaerobic conditions or by the addition of sulfhydryl compounds such as mercaptoethanol or thioglycolate The proteins of these organisms are peculiarly sensitive to inactivation by oxidation This may be a reflection of their primitive evolutionary state In higher aerobic species these protein SH— groups are folded into the center of the molecule and thus are protected from oxidation They are exposed when the protein is denatured

OXIDATIVE ASSIMILATION

Aerobic organisms oxidize only a portion of the substrate which they consume the remainder is converted to cell material In the presence of a limiting amount of a carbon (and energy) source oxygen consumption continues until all of the substrate is depleted from the medium following which it returns to the low endogenous level characteristic of resting cells (Fig 6) Calculation of the amount of oxygen consumed relative to the amount of substrate added generally will show that about half the substrate is oxidized the remainder of *substrate utilization is not accounted for* either by carbon dioxide production or oxygen consumption As an example in the case of glucose the equation for respiration

$$C_6H_{12}O_6 + 6O \longrightarrow 6CO + 6H\ O$$

requires the uptake of 6 moles of O for each mole of glucose consumed With most aerobic organisms the observed value will be closer to 3 than to 6 Oxidative assimilation of substrate is common to a wide

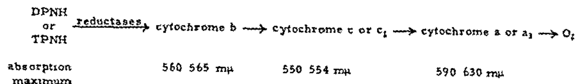

FIG 5 Role of the cytochromes in electron transport and their characteristic absorption maximum

plicated in succinate oxidation in *Coryne bacterium diptheriae*

In general very little is known about the precise function of the bacterial cytochromes Their role in respiration is evident from the fact that in most bacterial species which contain the cytochrome components respiration is inhibited by cyanide carbon monoxide or azide reagents which are known to block the functioning of the cytochrome system Bacterial cytochromes also participate in two other important physiologic functions namely nitrogen fixation and photosynthesis *Azotobacter* species which can carry out nitrogen fixation are among the richest sources of cytochromes Isolation and characterization of these pigments has been hampered by the difficulties in obtaining soluble preparations

The terminal oxidation system of bacteria resembles that of mammalian cells in its coupling to oxidative phosphorylation Respiratory particles capable of carrying out coupled oxidative phosphorylation have been isolated from many species of bacteria The P/O ratio obtained with these systems is usually less than with mammalian preparations but there is little doubt that this is a major energy yielding mechanism in aerobic microorganisms Like the mammalian system bacterial oxidative phosphorylation is uncoupled by dinitrophenol

The respiratory enzymes of bacteria appear to be associated with the cell membrane While there is no evidence for structures like the mitochondria of mammalian cells the chemical composition of the membrane which is rich in lipoprotein resembles that of the mammalian mitochondrial particle

The Flavin Enzymes

Many species of bacteria exhibit respiration which is not sensitive to carbon monoxide or cyanide Such species usually can be shown to contain considerable quantities of flavin and it is likely that their oxygen consumption is due to the action of flavoprotein enzymes Examples of microorganisms which show this type of respiration include the lactobacilli and the pneumococcus When these organisms are grown in the presence of air they produce hydrogen peroxide which can be detected either by its action on hemoglobin which it converts to a green pigment or by the benzidine peroxidase test (used for pneumococcus) These organisms are generally classified as faculative anaerobes and it is questionable whether their aerobic metabolism is of physiologic importance

Bacteria which lack cytochromes are generally also lacking in catalase and therefore are unable to remove hydrogen peroxide which is produced under aerobic conditions

Terminal Respiration Systems in Obligate Anaerobes

Many species of bacteria including species of clostridia, will when placed under aerobic conditions take up oxygen with the production of hydrogen peroxide but are either killed or inhibited from growth under these conditions It has been suggested that they are killed by the hydrogen peroxide which they produce since they lack catalase Two important objections may be raised to this hypothesis In the first place many species which lack catalase such as pneumococcus will continue to grow in air despite the accumulation of hydrogen peroxide Furthermore it has been established that the obligate anaerobes are not killed by oxygen itself nor by a product of oxygen metabolism but rather by the high oxidation reduction potential which results from the presence of oxygen Even obligate anaerobes can be

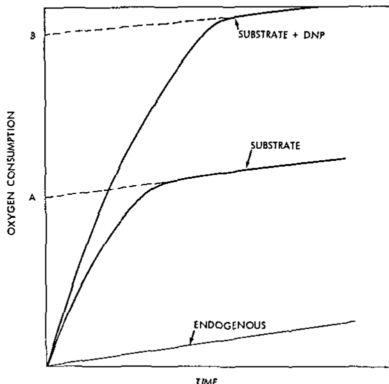

FIG 6 Schematic representation of oxidative assimilation and its uncoupling by dinitrophenol A and B represent the net oxygen uptake due to the substrate in the absence and the presence of dinitrophenol respectively

cultivated in the presence of oxygen if agents are added to maintain a low oxidation reduction potential Examples of such agents are ascorbic acid and cysteine both of which will facilitate growth of obligate anaerobes in the presence of oxygen It is noteworthy that these compounds will reduce oxygen to hydrogen peroxide and therefore tend to increase rather than decrease the concentration of this substance

A better hypothesis to account for the sensitivity of obligate anaerobes to oxygen is based on the sensitivity to oxidation of the proteins found in anaerobes Enzyme preparations from clostridia must be protected from oxygen by maintaining anaerobic conditions or by the addition of sulfhydryl compounds such as mercaptoethanol or thioglycolate The proteins of these organisms are peculiarly sensitive to inactivation by oxidation This may be a reflection of their primitive evolutionary state In higher aerobic species these protein SH— groups are folded into the center of the molecule and thus are protected from oxidation They are exposed when the protein is denatured

Oxidative Assimilation

Bacteria which lack cytochromes are generally also lacking in catalase and therefore are unable to remove hydrogen peroxide which is produced under aerobic conditions

Terminal Respiration Systems in Obligate Anaerobes

Many species of bacteria including species of clostridia, will when placed under aerobic conditions take up oxygen with the production of hydrogen peroxide but are either *killed or inhibited from growth under these conditions* It has been suggested that they are killed by the hydrogen peroxide which they produce since they lack catalase Two important objections may be raised to this hypothesis In the first place many species which lack catalase such as pneumococcus will continue to grow in air despite the accumulation of hydrogen peroxide Furthermore it has been established that the obligate anaerobes are not killed by oxygen itself nor by a product of oxygen metabolism but rather by the high oxidation reduction potential which results from the presence of oxygen Even obligate anaerobes can be

storage products resembling glycogen In many microorganisms the storage product is a polymer of β hydroxybutyric acid These polymers accumulate during the oxidation of glucose in the absence of nitrogen and account quantitatively for the substrate which is not oxidized When the cells are returned to medium containing nitrogen the storage products are consumed and converted to protein and other cell components

PATHWAYS OF CARBOHYDRATE METABOLISM

The Embden Meyerhof Pathway and the Citric Acid Cycle

Most bacteria oxidize substrates by pathways similar to those found in higher animals Glucose is metabolized by the Embden Meyerhof pathway (Fig 7) and the end product pyruvic acid is oxidized by the citric acid cycle (Fig 8) In most aerobic bacteria the citric acid cycle serves a dual function (1) it provides energy through the oxidation of reduced pyridine nucleotides by way of the cytochrome electron transport mechanism and (2) it provides precursors for the synthesis of amino acids Thus as is shown in Figure 8 arginine proline and lysine are derived from α ketoglutarate while aspartic acid isoleucine homoserine threonine and methionine are derived directly or indirectly from oxalacetate In bacteria lysine is derived from oxalacetate via diaminopimelic acid while in fungi it is produced from glutamate by way of α amino

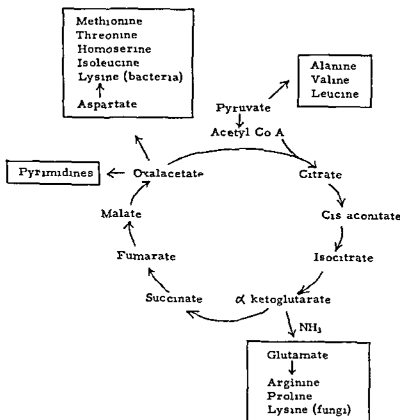

Fig 8 Origin of the amino acids and pyrimidines from citric acid cycle intermediates Primary fixation of NH_3 occurs only in the formation of glutamic acid from α ketoglutarate all other amino acids are formed via transamination reactions

variety of aerobic bacteria and substrates and can be blocked by dinitrophenol (DNP) This agent usually increases the initial rate of oxygen consumption but more striking is the fact that the total oxygen consumed is greater and in general will reach the theoretical value for complete oxidation This effect of DNP as an uncoupling agent for assimilation is analagous to its uncoupling of oxidative phosphorylation in mammalian cells The discovery of this effect of DNP in the uncoupling of assimilation in bacteria antedates its introduction as a tool for the study of oxidative phosphorlyation in mammalian cells

Assimilation of substrate by bacteria is a complex process Under growth conditions the assimilated substrate is converted to normal cell constituents protein lipid and nucleic acid However it does not follow that cells prevented from growth are unable to assimilate substrate Thus, in the absence of a source of nitrogen glucose and other substrates yield only about 50 per cent of the theoretical oxygen consumption the remainder of the substrate carbon is assimilated The most common products of substrate assimilation are polymers such as cellulose or a variety of capsular polysaccharides Bacteria commonly accumulate internal

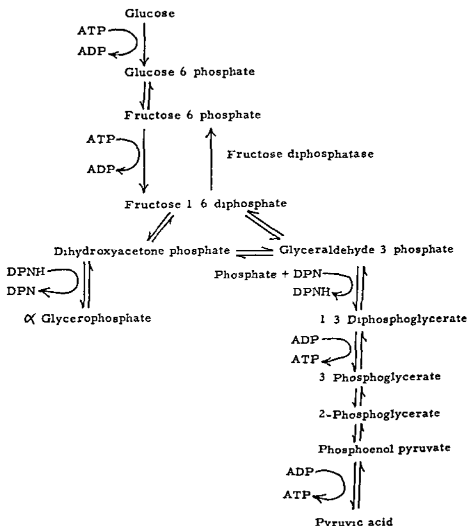

FIG 7 The Embden Meyerhof or Glycolytic Pathway

which can be assimilated via phosphoenol pyruvate Cells adapted to growth on acetate also contain a very active fructose 1 6 diphosphatase which permits the synthesis of hexose by a reversal of the glycolytic pathway (Fig 7)

Alternate Pathways of Carbohydrate Metabolism

Not all microorganisms metabolize carbo hydrate via the Embden Meyerhof pathway Deviations from this common pattern are frequently encountered in anaerobes and also in aerobic species carbohydrate metab olism may involve other pathways In this section we shall consider some of these alternate aerobic pathways

The pentose phosphate pathway, or hexo semonophosphate shunt, is present in nearly all species of bacteria whether or not they also contain the Embden Meyerhof pathway This pathway branches off from the Embden Meyerhof pathway at the level of fructose 6 phosphate which thus serves as a site for the action of cellular control mechanisms (Fig 10) Glucose 6 phosphate and fruc tose 6 phosphate are converted to pentose phosphate by one of two possible mech anisms In the first glucose 6 phosphate is oxidized directly at the C-1 position to yield 6 phosphogluconate which in turn is oxi dized to ribulose 5 phosphate The coenzyme for this oxidation is usually triphosphopyri dine nucleotide (TPN) although in some species of bacteria it is replaced by diphos phopyridine nucleotide (DPN) The primary product ribulose 5 phosphate is in equilib rium with ribose 5 phosphate the precursor of nucleic acid ribose or with xylulose 5 phosphate Xylulose 5 phosphate and ribose 5 phosphate are converted to sedoheptulose 7 phosphate and triose phosphate which in turn react to yield fructose 6 phosphate and erythrose 4 phosphate Finally to complete the cycle erythrose 4 phosphate can react with a second molecule of xylulose 5 phos phate to yield fructose 6 phosphate and triose phosphate In the oxidation of 6 phos phogluconate to ribulose 5 phosphate 1 mole of carbon dioxide is produced thus it is theoretically possible to pass a hexose phosphate molecule around the cycle 6 times and thereby to oxidize it completely to carbon dioxide and water It is to be noted that this series of reactions produces TPNH which unlike DPNH is not a substrate for the electron transport pathway and does not yield energy through oxidative phosphoryla tion None of the reactions of the pentose phosphate pathway will generate ATP and

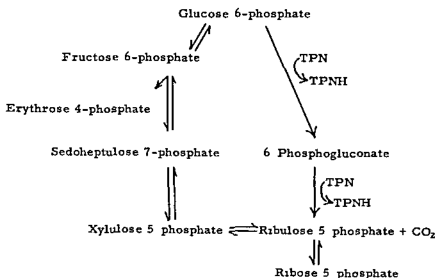

Fig 10 The Pentose Phosphate Pathway

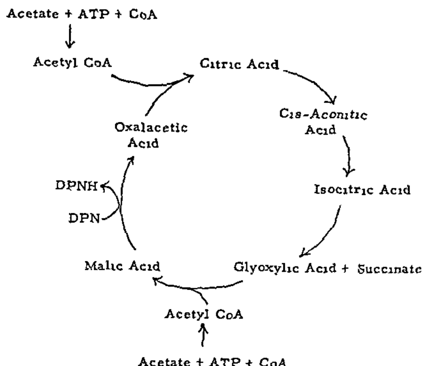

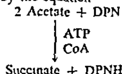

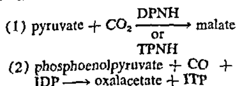

Fig 9 Conversion of acetate to succinate by the glyoxylate by pass The over all result may be expressed by the equation

adipic acid Pyruvate serves as a precursor of alanine valine and leucine In the absence *of amino acid or pyrimidine synthesis the* citric acid cycle is self sustaining with each turn of the cycle one equivalent of pyruvate is oxidized to yield 3 equivalents of carbon dioxide Oxalacetate is consumed in the formation of citrate and is regenerated in equivalent quantities However the removal of α ketoglutarate or oxalacetate for amino acid synthesis changes the character of the cycle since it can no longer sustain itself *when the pool of dicarboxylic acids* is depleted In order to maintain the cycle dicarboxylic acids must constantly be produced by other reactions Two such reactions are known

(1) pyruvate + $CO_2 \xrightarrow[\text{TPNH}]{\text{DPNH or}}$ malate

(2) phosphoenolpyruvate + CO + IDP $\longrightarrow$ oxalacetate + ITP

The first of these reactions catalyzed by the malic enzyme has been found in bacteria Thus far, the second carboxylase has not been detected Most of the CO produced in the citric acid cycle must be returned for the regeneration of dicarboxylic acids and it may be concluded that in bacteria the primary *function of the cycle is the* biosynthesis of amino acids rather than as a mechanism for the oxidation of pyruvate

The Glyoxylate Bypass

A special case exists in organisms using acetate for growth Theoretically acetate can *be converted to isocitrate by way of* acetyl CoA and the condensation reaction with oxalacetate However while it can be oxidized completely *by this series of reactions* it is impossible for it to be utilized for assimilation or biosynthesis Organisms which *grow on acetate as a sole carbon source* possess a modified citric acid cycle known as the glyoxylate bypass (Fig 9) Acetyl CoA condenses with oxalacetate *in the usual* way to form citric acid However isocitric acid is not oxidized to α ketoglutarate as in the citric acid cycle but is split in an aldolase type reaction to form glyoxylate and succinate Glyoxylate condenses with the second molecule of acetyl CoA to form malic acid which is converted to oxalacetic acid to complete the cycle This process provides a means for the net synthesis of C_4 acids

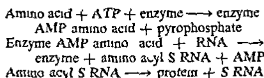
citric acid cycle For example citrate will support the growth of *Aerobacter aerogenes* but will not serve as a growth substrate for the closely related organism *Escherichia coli* The basis for this difference has been shown to be one of permeability *E coli* metabolizes internally produced citrate but is unable to take it up from the medium

In organisms lacking the citric acid cycle other mechanisms largely unknown are responsible for the synthesis of amino acids

Partial Oxidations

Many species of microorganisms derive energy by carrying out partial oxidations A classic example is the microorganism which catalyzes the oxidation of ethanol to acetic acid and was studied by Pasteur in his efforts to determine the cause of spoilage of wine Later Bertrand discovered the oxidation of polyols to ketoses by acetobacter a process which has been widely used by synthetic organic chemists for specific syntheses such as the formation of sorbose from sorbitol This is also the basis for the industrial production of gluconate and 2 ketogluconate These partial oxidations are accomplished by particulate enzymes which are coupled to energy production by unknown mechanisms In these organisms only a small fraction of the substrate is assimilated in this respect the processes resemble fermentation rather than respiration They probably represent a primitive respiration mechanism

FERMENTATION MECHANISMS



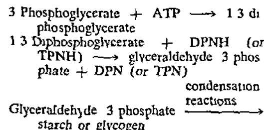
The Problem of Energy Production ATP and Reduced Pyridine Nucleotide

In contrast with aerobic metabolism where as much as 50 per cent of the substrate may be assimilated in fermenting cultures the bulk of the substrate utilized accumulates in the medium as end products of fermentation In the fermentation of a carbon compound even in growing cells as little as 5 per cent of the carbon may be utilized for the formation of cell constituents with the remainder being broken down (dissimulated) to provide energy This energy is in two main forms one is ATP the other is reduced pyridine nucleotide Several examples will serve to illustrate the manner in which these sources of energy may be utilized for the synthesis of cellular components

The hydrolysis of protein to its component amino acids is primarily an exergonic reaction and may be represented as follows

Protein + H O ⟶ amino acids + energy

On the other hand for the synthesis of proteins it is necessary that the amino acid be activated



Amino acid + ATP + enzyme ⟶ enzyme AMP amino acid + pyrophosphate
Enzyme AMP amino acid + RNA ⟶ enzyme + amino acyl S RNA + AMP
Amino acyl S RNA ⟶ protein + S RNA

There is some indication that the last step the conversion of amino acyl S RNA to protein may also require energy in the form of ATP or GTP

The following examples illustrate how reduced pyridine nucleotide may be used to drive synthetic reactions which would otherwise be exergonic We have considered already the cases of amino nitrogen formation and CO_2 fixation to yield dicarboxylic acids

α Ketoglutaric acid + TPNH + NH_3 ⟶ glutamic acid + TPN
Pyruvic acid + TPNH + CO_2 ⟶ malic acid + TPN

Another example is the synthesis of glucose from 3-carbon precursors which involves both pyridine nucleotides and ATP The essential energy requiring steps may be represented as follows

3 Phosphoglycerate + ATP ⟶ 1 3 diphosphoglycerate
1 3 Diphosphoglycerate + DPNH (or TPNH) ⟶ glyceraldehyde 3 phosphate + DPN (or TPN)
Glyceraldehyde 3 phosphate ⟶ (condensation reactions) starch or glycogen

This requirement for energy is illustrated best in photosynthesizing organisms in which energy produced by light is utilized for the formation of both TPNH and ATP Both

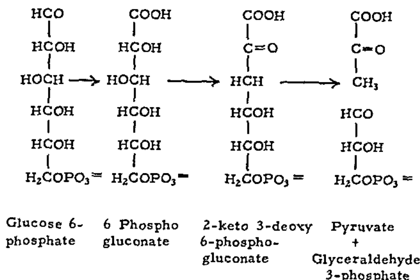


FIG 11 Glucose metabolism by the Entner Duodoroff Pathway Pyruvate and triose phosphate are further metabolized by the Embden Meyerhof pathway and the citric acid cycle

it is unlikely that it operates as a mechanism for the production of this form of cellular energy However the pathway is important for the production of another form of energy useful to the cells reduced triphosphopyridine nucleotide (TPNH) which is specifically required for a number of important synthetic processes For example it is the coenzyme utilized in the formation of C_4 acids from pyruvate and CO

$$\text{pyruvate} + CO + \text{TPNH} \longrightarrow \text{malate} + \text{TPN}$$

It also plays an important role in the formation of amino nitrogen since it can serve in the reaction catalyzed by glutamic dehydrogenase

$$\alpha\ \text{ketoglutarate} + \text{TPNH} + NH_3 \longrightarrow \text{glutamate} + \text{TPN}$$

In addition to these biosynthetic processes TPNH is known to be required for the synthesis of other reduced compounds such as fatty acids and sterols

In addition to the formation of TPNH the oxidative pathway also functions in the production of pentose for the synthesis of nucleic acids and nucleotides This can arise either by the oxidation reactions by way of 6 phosphogluconate or directly from fructose 6 phosphate by a reversal of the reactions in the left hand part of the scheme (Fig 10) The available evidence suggests that in most microorganisms pentose phosphate is formed by both mechanisms Therefore the cycle is not operating exclusively in the clockwise direction but rather in the 2 branches of the cycle the flow is in the direction from hexose monophosphate to pentose phosphate

The Entner Doudoroff Pathway This is another important alternate pathway in microorganisms (Fig 11) The first oxidative step is the same as in the pentose phosphate pathway but 6 phosphogluconate is not further oxidized to pentose phosphate but instead is split to form pyruvate and glyceraldehyde 3 phosphate The pathway was first discovered in pseudomonas It has also been detected in the *Enterobacteriaceae* and probably will be found to occur as well in other species It also occurs as a fermentation mechanism

THE DISTRIBUTION OF THE CITRIC ACID CYCLE

The presence of the citric acid cycle in bacteria has been the subject of considerable controversy and definite conclusions may be drawn with respect to only a few microorganisms It appears to function in the *Enterobacteriaceae* along with the Embden Meyerhof pathway but is absent is aerobacter and related species It probably does not occur except in greatly modified forms in most anaerobes Work in this area has been hampered by the fact that many cells are impermeable to intermediates of the

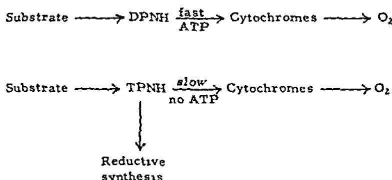

Fig 13 Oxidation of the pyridine nucleotides and production of energy

and fermentation while at the same time it was involved in the oxidation steps of the citric acid cycle and therefore of respiration On the other hand the most important steps requiring TPN were those of the pentose phosphate pathway already mentioned and isocitric dehydrogenase It has become increasingly clear that these reactions are important in generating reduced TPN for essential reduction mechanisms These reduction mechanisms were not required in the primitive atmosphere which itself was reducing and when the seas were filled with reduced cell precursors Early organisms which depended on fermentation must have possessed only a single coenzyme DPN which functioned in fermentation pathways such as the Embden Meyerhof pathway With the appearance of oxygen in the atmosphere and the consequent depletion of reducing substances of the hydrosphere the need arose to provide mechanisms for the formation of reduced cytoplasmic components and also for a source of energy less wasteful of the dwindling supply of organic materials This led to the appearance of respiratory mechanisms catalyzing the oxidation of DPNH by molecular oxygen A new coenzyme was needed to preserve the reducing potential now required by the cell This need was filled by TPNH which is not in catalytic equilibrium with oxygen In the intact metabolizing cell most of the DPN is present in the oxidized form while TPN is present largely in the reduced form Thus a cell can exist in equilibrium with oxygen and therefore at a very high oxidation reduction potential and yet maintain some of its components (such as *TPNH*) at a very low oxidation reduction state According to this hypothesis anaerobic organisms have no need for the TPN reduction mechanism and indeed it is absent in clostridia

Examples of Fermentation Pathways

Alcoholic fermentation is common in yeasts where it has been shown to proceed by a modification of the Embden Meyerhof

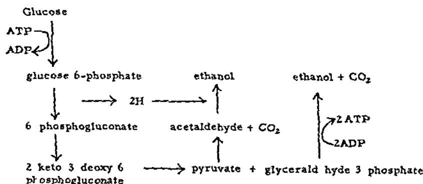

Fig 14 Ethanol fermentation of *Pseudomonas lindneri*

forms of energy are expended in accomplishing the endergonic conversion of phosphoglyceric acid to glyceraldehyde 3 phosphate (Fig 12) Fructose 6 phosphate is partially (1/6) converted to starch The remainder (5/6) is needed to regenerate the CO acceptor ribulose 1,5 diphosphate This mechanism operates in photosynthetic and chemosynthetic bacteria as well as in higher plants

Therefore in considering fermentation *mechanisms it is important to bear in mind* the requirement of the organism for these two distinct sources of energy It is also necessary to maintain balanced oxidation reductions Lavoisier first introduced the concept of fermentation when he proposed that substances rich in oxygen might undergo internal oxidations in which one part of the molecule would emerge with less oxygen and another part would become oxygen rich Thus, *Lavoisier noted that* sugar which contains 53 per cent oxygen could be fermented to a mixture of ethanol containing 35 per cent oxygen, and carbon dioxide containing 70 per cent oxygen Therefore fermentation was nothing more than an internal oxido reduction Lavoisier also proposed that all of the atoms of carbon hydrogen and oxygen must be accounted for thus stating the law of conservation of mass *The balancing of fermentation equations is* accomplished most conveniently by equating the number of hydrogen atoms produced at various stages of the process to the number consumed

Evolutionary Relation of Fermentation and Respiration Pathways

It is now generally accepted that the early atmosphere in which life originated was highly reducing in nature and devoid of oxygen and that early forms of life obtained their energy through fermentation *mechanisms Thus we may assume that* fermentation was an early evolutionary development and that respiration appeared only after the development of plant life and the resultant appearance of oxygen in the atmosphere It is instructive to consider the physiologic role of the 2 pyridine nucleotides DPN and TPN in the light of this concept DPN (cozymase) was first recognized as the coenzyme required for alcoholic fermentation TPN on the other hand was discovered in connection with the oxidation of glucose 6 phosphate to 6 phosphogluconate and first was *believed to be the coenzyme of* respiration However, with the development of our understanding of the respiratory mechanism it became clear that the substrate for respiration was reduced DPN rather than reduced TPN The oxidation of DPNH in mitochondria was found to be a rapid reaction coupled to the esterification of ATP On the other hand the oxidation of TPNH was relatively sluggish and proceeded without coupled phosphorylation (Fig 13) These discoveries led to a re evaluation of the role of the 2 pyridine nucleotides There remained little doubt about the role of DPN as the specific coenzyme of glycolysis

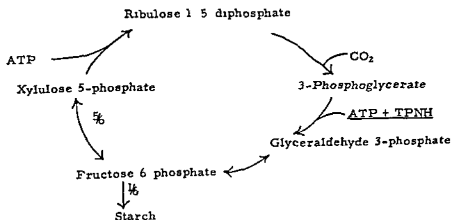

Fig 12 Energy requirement for photosynthesis Note that ATP and TPNH are employed to drive the irreversible steps *so that the cycle proceeds in the* clockwise direction

in higher organisms and the Embden Meyerhof pathway has been shown to be im portant in these organisms

Heterolactic fermentations are those pro ducing other products in addition to lactic acid They are often called mixed acid fermentations The additional products in clude ethanol acetic acid formic acid suc cinic acid carbon dioxide hydrogen butyric acid and others The metabolic origin of these fermentation products is outlined in Figure 15 In general in these fermenta tions glucose is converted to pyruvate by the usual steps of the Embden Meyerhof path way A large variety of products can be formed from pyruvate Acetoin a common product of fermentation is formed from 2 moles of pyruvate in a condensation catalyzed by the carboxylase type enzymes In some instances this is reduced to yield 2 3 butane diol Pyruvate can also be con verted by carboxylation to oxalacetate which is the precursor of succinic acid and propi onic acid In the coli aerogenes group a major pathway of pyruvate degradation in volves its cleavage to acetyl CoA and formic acid which is a common fermentation product in these organisms In the clostridia pyruvate is broken down by a different re action which produces acetyl CoA hydrogen and carbon dioxide

In each fermentation the balance of hy drogen equivalents must be maintained in cluding the 4 equivalents produced in the conversion of glucose to pyruvate This is illustrated best by the fermentation of hexose and pentose in lactobacilli Hexose fermenta

TABLE 1 PRODUCTS OF GLUCOSE FERMENTATION WITH *Bacillus subtilis*

PRODUCTS	MMOLES/100 MMOLES OF GLUCOSE
2 3 Butanediol	55

Glycerol	57
Ethanol	8
Formic acid	1+
Acetic acid	tr
Lactic acid	18
Succinic acid	1+
Carbon-dioxide	118
Hydrogen	tr

tion may yield equivalent quantities of lactic acid ethanol and CO but in the fermenta tion of pentose no CO is formed and acetic acid is produced instead of ethanol In the fermentation of glucose by *Bacillus subtilis* the products formed are in approxi mately the proportions shown in Table 1 For each glucose molecule fermented we can account for 5 8 atoms of carbon 13 1 of hydrogen and 5 8 of oxygen The missing carbon and oxygen atoms are present in small quantities of acetoin formic acid and succinic acid

Heterolactic Fermentation Lactobacillus Type In many species of lactobacilli the fermentation balance is represented by the equation

Glucose → lactic acid + ethanol + CO

In *Leuconostoc mesenteroides* an organism closely related to the lactobacilli this re

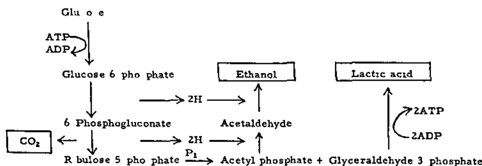

FIG 16 Hexose fermentation in *Leuconostoc mesenteroides* The fermentation products are outlined in rectangles

pathway (Fig 7) Pyruvate formed in the last step is decarboxylated to acetaldehyde and CO Then acetaldehyde is reduced to lactate The hydrogen atoms (or electrons) produced as DPNH in the oxidation of 3 phosphoglyceraldehyde are utilized for this reduction

Pure alcoholic fermentation is rare in bacteria The organism *Pseudomonas lindneri* appears to carry out a classic Embden Meyerhof type of ethanolic fermentation

$$C_6H_{12}O_6 \longrightarrow 2\,C_2H_5OH + 2\,CO_2$$

but in fact this organism utilizes the Entner Doudoroff pathway (Fig 14) The hydrogen balance is preserved since 2 atoms of hydrogen formed in the oxidation of glucose 6 phosphate are required for the reduction of one equivalent of acetaldehyde A similar balance exists in the oxidation of glyceraldehyde 3 phosphate and the reduction of the second molecule of ethanol ATP is produced in low yield two equivalents are produced in the conversion of glyceraldehyde 3 phosphate to ethanol and one of these is required for the initial phosphorylation of glucose

Homolactic Fermentation Fermentation mechanisms which give rise to lactic acid as the sole product are common in microorganisms They occur in pneumococcus as well as in many species of lactobacilli and streptococci In general the pathways may be assumed to be identical with those found

Glucose
Lactic acid ← 2H — Pyruvic acid — $-CO_2$ → Acetaldehyde — 2H → Ethanol
Pyruvic acid — CO_2 → Oxalacetic acid — 2H → Malic acid → Succinic acid — CO_2 → Propionic acid
Pyruvic acid — $-CO_2$ → Acetolactic acid — $-CO_2$ → Acetoin — 2H → 2 3 Butanediol
CO_2 2H
Clostridia: H_2 + CO_2 + Acetyl CoA
Coli-Aerogenes: Acetyl CoA + Formic acid
Acetyl CoA → Acetic acid
Acetyl CoA — 4H → Ethanol
Acetyl CoA → Acetoacetic acid — 4H → Butyric acid — 2H → Butanol
Acetoacetic acid — CO_2 → Acetone — 2H → Isopropanol

FIG 15 Origin of products in mixed acid fermentations Final products are indicated in the rectangles (Wood W A *in* Gunsalus I C and Stanier R Y (eds) The Bacteria Vol II p 82 New York Academic Press 1961)

tion reduction reactions appear only at the last steps when two equivalents of pyruvate are converted to one of butyrate and 2 of carbon dioxide. The formation of butyrate by this series of reactions is a common fermentation reaction in clostridia.

In the fermentation of cysteine hydrogen sulfide is a product. Fermentations of this amino acid yield ammonia, carbon dioxide, acetate, formate, hydrogen and butyrate in addition to hydrogen sulfide.

Tryptophan is converted in part to indole and skatole, characteristic products of fermentation of mixtures of amino acids containing this substance.

Fermentation of Pairs of Amino Acids

Many species of clostridia are unable to grow on single amino acids but grow well on protein hydrolysates or amino acid mixtures. These organisms derive energy from coupled oxidation reduction reactions between pairs of amino acids, a type of fermentation known as the Stickland reaction. A typical example is the fermentation of a mixture of alanine and glycine by *Clostridium sporogenes*:

$$\text{Alanine} + 2\ \text{glycine} + 2\ H_2O \longrightarrow 3\ NH_3 + 3\ CH_3COOH + CO_2$$

In this fermentation carbon dioxide is derived from the alanine residue by an oxidative process while glycine is reduced directly to acetic acid and ammonia. A number of amino acids serve specifically as reductants in the Stickland reaction while others seem to act specifically as oxidants (Table 2). Characteristic of the Stickland

Table 2 Redundants and Oxidants in the Stickland Reaction

Reductants	Oxidants
Alanine	Glycine
Leucine	Proline
Isoleucine	Hydroxyproline
Valine	Ornithine
Histidine	Arginine
Phenylalanine	Tryptophan

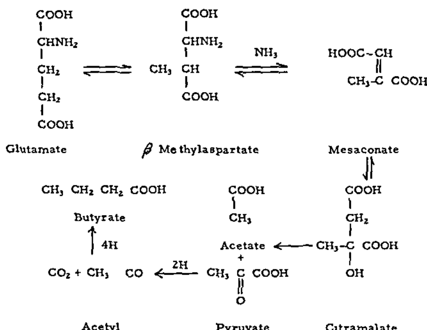

Fig 18 Pathway of glutamate fermentation (H. A. Barker *in* Gunsalus, I. C. and Stanier, R. Y. (eds.) The Bacteria, Vol. II, p. 167, New York: Academic Press, 1961)

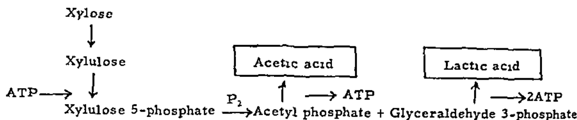

FIG 17 Pentose fermentation in *Lactobacillus plantarum*

sults from a series of reactions which constitute a modification of the hexose monophosphate shunt or pentose phosphate pathway (Fig 16) The 2 pairs of protons produced in the oxidation of glucose 6 phosphate and 6 phosphogluconate are utilized for the 2 step reduction of acetyl phosphate to ethanol In other species of lactobacilli fermentation proceeds according to the following balance

3 Fructose → 2 mannitol + lactic acid + acetic acid + CO

Since acetic acid and CO are the end products rather than ethanol and CO_2 2 pairs of protons must be disposed of in some other process This is provided by the reduction of 2 additional moles of fructose to mannitol thereby maintaining the over all fermentation balance

In the fermentation of pentoses by the same organisms the over all fermentation can be expressed as

Pentose → acetic acid + lactic acid

The fermentation mechanism resembles that shown in leuconostoc (Fig 17) Pentose is cleaved to form acetyl phosphate and triosphosphate which are the precursors of acetic acid and lactic acid respectively This type of fermentation yields 2 net equivalents of ATP per mole of pentose, the same as in the homolactic fermentation of glucose by this organism

FERMENTATION OF NITROGEN CONTAINING COMPOUNDS

Bacteria can grow on a variety of nitrogen containing compounds particularly amino acids purines and pyrimidines These provide not only energy but also carbon and nitrogen The growth of bacteria on nitrogen containing compounds generally has been associated with the production of volatile products which produce characteristic odors this type of fermentation was called putrefaction In general particularly among aerobic microorganisms amino acids are converted to intermediates of the Embden Meyerhof pathway or citric acid cycle and fermented and oxidized in the usual way Thus alanine and glutamic acid are oxidatively decarboxylated to yield pyruvic acid and α ketoglutaric acid respectively The fermentation of amino acids may involve *novel pathways which are of interest because* of the pathogenic nature of some of these microorganisms and because of the information which has been gained from the study of these pathways Thus the first evidence for the role of vitamin B_1 in intermediary metabolism was obtained through a study of the bacterial fermentation of glutamic acid

Species of bacteria which are capable of fermenting single amino acids fall primarily into 2 groups the anaerobic spore formers (clostridia) and the anaerobic cocci (micrococcus and diplococcus) A few facultative aerobes including *Escherichia coli* are able to ferment some amino acids The pathway for the fermentation of glutamate in the anaerobic spore forming organism *Clostridium tetanomorphum* is shown in Figure 18 The major products are butyric acid acetic acid and carbon dioxide The first step the conversion of glutamate to β methyl aspartate is of particular interest because of the roles of the coenzyme form of vitamin B_1 This coenzyme differs from the vitamin B_1 in having an adenosine residue attached to the cobalt molecule in place of the cyanide group The coenzyme has also been shown to function in the formation of propionic acid from succinic acid (Fig 15)

In this fermentation of glutamate oxida

this series of reactions first led to the elucidation of the role of folic acid The organism *Clostridium cylindrosporum* is remarkable in that it can grow only on the purines xanthine uric acid or guanine It is unable to use other compounds including carbohydrates for growth The fermentation of xanthine proceeds by a series of hydrolytic reactions (Fig 19) leading eventually to formiminoglycine This reacts with the coenzyme tetrahydrofolic acid to yield glycine and formimino tetrahydrofolic acid The latter is converted to 10 formyl tetrahydrofolic acid by way of the 5 10 methenyl derivative In the conversion of 10 formyl tetrahydrofolic acid to the coenzyme tetrahydrofolic acid and formic acid ATP is produced This is the first and perhaps the only energy yielding step in the fermentation It is remarkable that *Clostridium cylindrosporum* is able to fulfill all of its requirements by this series of reactions and from glycine formic acid and ATP can produce all of the complex components of the cell The fermentation of xanthine by *Clostridium cylindrosporum* has an interesting parallel in the metabolism of histidine by mammals This amino acid is ultimately converted to formimino glutamic acid (Fig 20) The conversion of formiminoglutamic acid to glutamic acid requires the conezyme tetrahydrofolic acid and yields the same intermediate formed in the bacterial fermentation In folic acid deficiency in man this reaction is blocked and large quantities of formiminoglutamic acid may be excreted This provides a sensitive and rapid method for detecting folic acid deficiency

Enrichment Culture

As may be evident from the foregoing discussion of fermentation reactions bacteria as a group are capable of utilizing any organic compound which is found in nature This has led to the development of the enrichment culture technic for the isolation of new organisms In this procedure organisms are selected which are capable of growing on the compound provided as the sole carbon source The enrichment culture technic has been used for studies of pathways of breakdown of metabolites and also to develop specific hydrolytic enzymes for the degradation of macromolecules In general bacteria will not use complex macromolecules but will first break these down to their monomeric components For example proteins will be utilized only after hydrolysis to amino

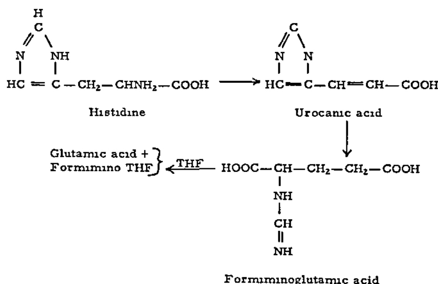

FIG 20 Role of tetrahydrofolic acid in the breakdown of histidine

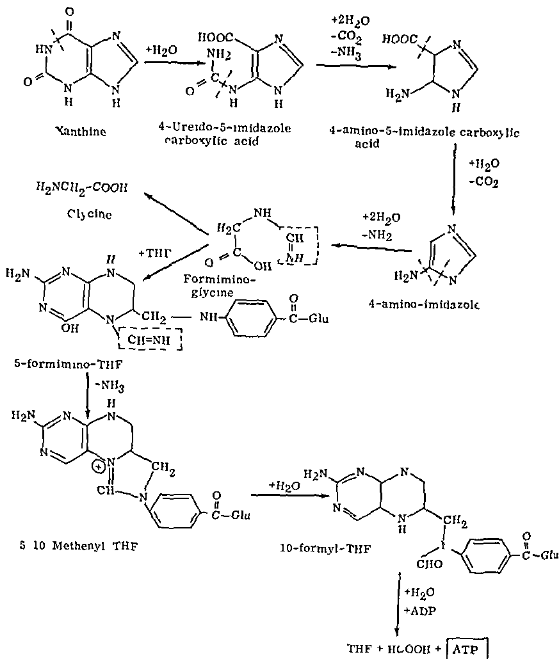

FIG 19 Fermentation of purines in *Cl cylindrosporum* THF represents tetrahydrofolic acid

reaction is the fact that the oxidants are converted directly to reduced products e g glycine to acetate proline to δ amino valerate etc For the most part the reactions leading directly to the formation of energy (ATP) in the Stickland reaction remain to be elucidated

FERMENTATION OF HETEROCYCLIC COMPOUNDS

The fermentation of purines by clostridia is of interest because it illustrates the com plex mechanisms by which organisms may derive energy from fermentation and because

may be detected by its odor or by the deposition of iron sulfide in suitable media

SYNTHESIS OF MACROMOLECULES

Bacterial cells contain nucleic acid protein carbohydrate and lipid all of which must be synthesized in more or less definite proportion in order to maintain normal cell growth

The Nucleic Acids

The synthesis of DNA is the result of the action of the enzyme DNA polymerase which catalyzes the formation of chains of deoxyribose nucleotides from nucleoside triophosphates This synthesis does not occur in a random fashion but is directed by the DNA present in the cell in such a manner that the new DNA synthesized is a precise copy of that which is originally present A schematic representation of this synthesis is shown in Figure 21 The enzyme responsible for this reaction DNA polymerase has been well characterized but the manner in which it acts inside the cell is little understood Double stranded DNA such as is normally isolated from living cells is a very poor primer and must be altered by heating or by enzyme action in order to serve effectively as a primer Once the two strands of DNA are separated each appears to act independently catalyzing the formation of a complementary strand Thus the presence of adenylic acid in the priming strand determines that thymidylic acid is inserted in the newly synthesized strand and vice versa Similarly guanine in DNA primes for the incorporation of cytosine As a consequence the over all composition of the newly synthesized DNA is an exact duplicate of that which is provided as primer

DNA synthesis appears to be the site of action of several antibiotics For example the antibiotic mitomycin inhibits completely the synthesis of DNA in intact cells while

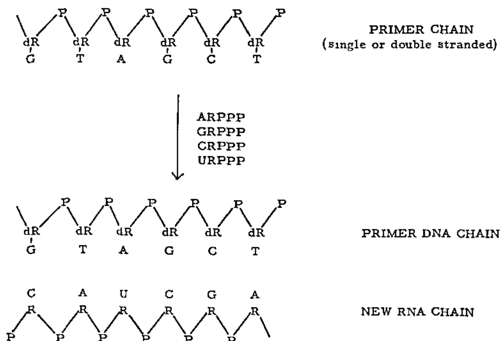

Fig 22 Schematic representation of DNA—primed RNA synthesis The symbols R and ARPPP etc represent ribose and ribose nucleoside triphosphates As in the case of DNA synthesis inorganic pyrophosphate is the other product

acids nucleic acids only after breakdown to nucleosides or purines and pyrimidines *polysaccharides* only after hydrolysis to the component monosaccharides The *hydrolytic* enzymes which microorganisms produce for this purpose have provided useful tools for the study of the structure of macromolecules

USE OF FERMENTATION PATTERNS IN THE CLASSIFICATION OF MICROORGANISMS

The classification of bacteria depends not only on morphologic examination but also to a considerable extent on the biochemical capabilities and behavior For example closely related species may be distinguished from each other by their ability to ferment specific sugars such as mannose galactose or lactose Specific media have been devel oped for these purposes when the substrate is a carbohydrate the method may depend on the production of acid through fermenta tion In aerobic organisms it is convenient to measure growth of the organism Among the staphylococci, the pathogenic species commonly will ferment mannitol while non pathogens are usually lacking in this capacity In the case of the enteric organisms shigella and salmonella species are commonly lactose negative whereas the closely related *Escherichia coli* is lactose positive As mentioned previously *Escherichia coli* can be distin guished from *Aerobacter aerogenes* by the fact the the latter is able to ferment citrate

Bacterial classification is also aided by examination of the types of products pro duced The production of gas may be due to the presence of the enzyme formic hy drogen lyase which catalyzes the formation of hydrogen and CO from formate

$$HCOOH \longrightarrow H + CO$$

The formation of acetoin is the basis for the *Voges Proskauer* reaction which helps to distinguish *Aerobacter aerogenes* Among the *Enterobacteriaceae* only *Escherichia coli* is capable of producing indole from trypto phan Another product which permits the characterization of many organisms is their capacity to form H S from cysteine This

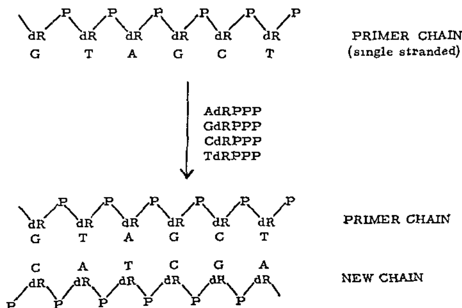

FIG 21 Schematic representation of DNA synthesis The symbols dR and AdRPPP etc represent deoxyribose and the deoxyribose nucleoside triphos phates The dotted lines connecting the bases represent hydrogen bonds Pyrophosphate is produced in the reaction

Closely related species of microorganisms differ in the location of methyl groups in the RNA and the DNA molecules

PROTEIN SYNTHESIS

The mechanism of protein synthesis in *microorganisms is considerably* better under stood than this mechanism in animal cells and may be represented by the scheme shown in Figure 23 The first step is the activation of the amino acid in the reaction with ATP to form the intermediate adenylyl amino acid This does not exist in free form but as an enzyme bound intermediate from which is transferred to a specific transfer or S RNA Specific S RNA s and specific activating enzymes exist for each amino acid thus tyrosine is converted to tyrosyl S RNA by one enzyme system and leucine to the corresponding leucyl S RNA by a distinct enzyme system and so on for each of the 18 amino acids In the reaction catalyzed by the amino acid activating enzymes inorganic pyrophosphate is produced and as in the case of DNA and RNA synthesis it is the hydrolysis of inorganic pyrophosphate that provides the driving force for what other wise would be a highly reversible process Loaded S RNA carries the amino acid to the ribosome where it is incorporated into the protein chain

Proteins which are synthesized at the ribosome possess amino acid sequences which are dictated by the information stored in the bacterial chromosome The transfer of this information from the chromosome to the ribosome involves the participation of mes senger RNA which receives the genetic code *from the DNA and transmits it to the ribo* some The language used in this system con sists of 3 letter words spelled out by the bases in the nucleic acid Thus a sequence of 3 uridine residues in the nucleic acid desig nated as UUU carries the message for the incorporation of phenylalanine The se quence AAG codes for the incorporation of glutamic acid (Table 3) In vitro synthesis of RNA by the enzyme DNA RNA poly merase results in the production of 2 strands of RNA each of which is a copy of one of the 2 DNA strands in vivo however only a single strand of DNA is copied and only a single strand of messenger RNA is pro duced This messenger RNA interacts with ribosomes forming aggregates known as *polysomes* which appear to be the actual site of protein synthesis The bacterial system appears to differ from that found in animal tissues in that the messenger RNA in bac teria is extremely unstable and protein syn thesis depends on the constanct production of new messenger RNA As a result, the entire system for protein synthesis is under close regulation and control and the syn thesis of any protein can be turned on or off almost instantly as conditions require The breakdown of messenger RNA may be related to the presence of polynucleotide phosphorylase which is found in bacterial cells but has not been positively detected in mammalian cells Polynucleotide phosphory lase catalyzes the reversible phosphorolysis of RNA to nucleoside triphosphates It has been employed in the synthesis of poly *nucleotides for study of the amino acid code*

TABLE 3 TRIPLET CODE LETTERS FOR AMINO ACID INCORPORATION GOVERNED BY MESSENGER RNA

(In each case only one of the several code letters has been given)

AMINO ACID	TRIPLET	AMINO ACID	TRIPLET
Lysine	AAA	Arginine	GAA
Asparagine	CAA	Methionine	UGA
Histidine	ACC	Glycine	GAG
Glutamine	AAC	Cysteine	GUU

From Jukes BBRC *10* 155 (1963)

Recognition of the code for protein syn thesis appears to reside in the specific S RNA s which in turn interact with the specific amino acid activating enzymes The nature of this recognition system remains obscure but the hypothesis has been put forward that there is a triplet of nucleotides in S RNA which is complementary to the code triplet in messenger RNA and that the interaction of these complementary sets of nucleotides is responsible for the attachment of S-RNA at the proper location of the ribosome

A number of antibiotics interfere with

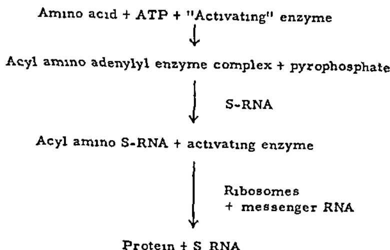

FIG 23 Pathway of amino acids in protein synthesis S RNA represents soluble" or transfer RNA The ribosomes are aggregated by messenger RNA into polysomes which are the site of protein synthesis

it leaves the synthesis of RNA and protein relatively unimpaired In cells infected with bacteriophage the effect of *mitomycin on* DNA synthesis is specific for host DNA and replication of viral DNA is not blocked This may be related to an effect of mitomycin in preventing separation of the strands of host DNA Actinomycin also interferes with DNA replication in intact cells, but this process is not so sensitive as is the synthesis of RNA

Bacteria contain several forms of RNA including messenger RNA soluble or transport RNA and ribosomal RNA Of these only the synthesis of messenger RNA is well understood This is formed in a reaction which strongly resembles the formation of DNA and is catalyzed by the enzyme DNA-RNA polymerase (Fig 22) In this reaction again DNA serves as a primer and a chain of ribonucleotides is formed with ribonucleoside triphosphates as the precursors Each base in the DNA chain directs the incorporation of the complementary base in the RNA chain adenosine in DNA governs the incorporation of uridylic acid in RNA and guanine the incorporation of cytidylic acid RNA formed in this reaction unlike the bulk of the cellular RNA possesses the same base composition as does DNA It has been established that this type of RNA turns over rapidly in bacterial cells and serves as the messenger which carries information from the gene to the site of protein synthesis (see below) Unlike DNA-polymerase RNA polymerase can be primed with either double-stranded or single *stranded DNA The activity of this enzyme* is extremely sensitive to actinomycin and it would appear that this is the primary site of action of this drug in bacterial cells

Two other types of RNA are found in bacteria These are ribosomal RNA associated with nucleoprotein particles and the so-called soluble or transport RNA The mechanism of formation of these species of RNA is not established but it has been proposed that certain regions of the chromosome specifically code for the formation of transfer and of ribosomal RNA Since these are very small regions their base composition does not reflect that of the total chromosomal DNA Transport RNA and to a lesser extent other species of RNA and DNA contain methylated bases such as thymine methyl adenine and methyl cytosine These methyl groups unlike the methyl group of thymine in DNA are derived from methionine rather than from C 1 residues of the formyl folic acid type In this respect thymine riboside differs from the corresponding deoxyriboside The methyl groups in RNA are introduced into RNA after it has been polymerized and not during synthesis of the mononucleotides The function of these unusual bases in DNA and RNA is not understood but they may be related to species specificity since the enzymes responsible for their introduction into preformed nucleic acid are highly specific

Closely related species of microorganisms differ in the location of methyl groups in the RNA and the DNA molecules

PROTEIN SYNTHESIS

The mechanism of protein synthesis in microorganisms is considerably better understood than this mechanism in animal cells and may be represented by the scheme shown in Figure 23 The first step is the activation of the amino acid in the reaction with ATP to form the intermediate adenylyl amino acid This does not exist in free form but as an enzyme bound intermediate from which is transferred to a specific transfer or S RNA Specific S-RNA s and specific activating enzymes exist for each amino acid thus tyrosine is converted to tyrosyl S RNA by one enzyme system and leucine to the corresponding leucyl S RNA by a distinct enzyme system and so on for each of the 18 amino acids In the reaction catalyzed by the amino acid activating enzymes inorganic pyrophosphate is produced and as in the case of DNA and RNA synthesis it is the hydrolysis of inorganic pyrophosphate that provides the driving force for what otherwise would be a highly reversible process Loaded S RNA carries the amino acid to the ribosome where it is incorporated into the protein chain

Proteins which are synthesized at the ribosome possess amino acid sequences which are dictated by the information stored in the bacterial chromosome The transfer of this information from the chromosome to the ribosome involves the participation of messenger RNA which receives the genetic code from the DNA and transmits it to the ribosome The language used in this system consists of 3 letter words spelled out by the bases in the nucleic acid Thus a sequence of 3 uridine residues in the nucleic acid designated as UUU carries the message for the incorporation of phenylalanine The sequence AAG codes for the incorporation of glutamic acid (Table 3) In vitro synthesis of RNA by the enzyme DNA RNA polymerase results in the production of 2 strands of RNA each of which is a copy of one of the 2 DNA strands in vivo however only a single strand of DNA is copied and only a single strand of messenger RNA is produced This messenger RNA interacts with ribosomes forming aggregates known as *polysomes* which appear to be the actual site of protein synthesis The bacterial system appears to differ from that found in animal tissues in that the messenger RNA in bacteria is extremely unstable and protein synthesis depends on the constanct production of new messenger RNA As a result the entire system for protein synthesis is under close regulation and control and the synthesis of any protein can be turned on or off almost instantly as conditions require The breakdown of messenger RNA may be related to the presence of polynucleotide phosphorylase which is found in bacterial cells but has not been positively detected in mammalian cells Polynucleotide phosphorylase catalyzes the reversible phosphorolysis of RNA to nucleoside tripho phates It has been employed in the synthesis of poly nucleotides for study of the amino acid cod

TABLE 3 TRIPLET CODE LETTERS FOR AMINO ACID INCORPORATION GOVERNED BY MESSENGER RNA

Recognition of the code for protein synthesis appears to reside in the specific S RNA s which in turn interact with the specific amino acid activating enzymes The nature of this recognition system remains obscure but the hypothesis has been put forward that there is a triplet of nucleotides in S RNA which is complementary to the code triplet in messenger RNA and that the interaction of these complementary sets of nucleotides is responsible for the attachment of S-RNA at the proper location of the ribosome

A number of antibiotics interfere with

various steps in protein synthesis Chloramphenicol and puromycin block the transfer of amino acid from S RNA to the ribosomal protein synthesizing system Actinomycin as was pointed out previously interferes with the synthesis of messenger RNA and indirectly inhibits protein synthesis However it is noteworthy that not all protein synthesis is stopped by actinomycin Streptomycin also interferes with protein synthesis Streptomycin is known to combine with nucleic acids and it may combine with messenger RNA *thus interfering with the association* of this material with the ribosomes Streptomycin can be shown to inhibit the last step in protein synthesis in vitro furthermore ribosomes from streptomycin resistant strains of bacteria are not inhibited by the low levels of streptomycin which affect ribosomes of sensistive strains

Synthesis of Structural Polysaccharides

Bacterial cell walls and capsules contain many types of polysaccharides and the generalization can be made that the precursors of these polymers are the so called sugar nucleotides Some species of bacteria contain a substance closely resembling glycogen which probably is synthesized by the mechanism similar to that responsible for glycogen and starch synthesis in other cells

$$\text{UDP glucose} + (\text{glucose polymer}) \rightleftharpoons (\text{glucose polymer})_{n+1} + \text{UDP}$$

In this way large polysaccharides can be built up provided that the proper primers are present. Virulent strains of pneumococcus contain a variety of polysaccharides which provide the basis of group classification These complex heteropolysaccharides contain one or more of the following sugars N acetyl glucosamine galacturonic acid galactose glucose fucose and rhamnose Type III pneumococcus polysaccharide which appears to be polyglucuronic acid is built up by condensation of UDP glucuronic acid units Other precursors of pneumococcal polysaccharide are UDP N acetyl glucosamine and UDP galacturonic acid

Gram negative organisms, particularly those belonging to the *Enterobacteriaceae* also contain complex lipopolysaccharides in the cell wall This lipopolysaccharide complex *is part of the bacterial endotoxin and* O antigen and provides the basis for the Kaufmann White classification scheme for pathogenic strains Here again as in the case of pneumococcus polysaccharide the structure is built up by the successive addition of specific sugars in the form of sugar nucleotides, to the appropriate precursor The specific arrangement of sugars in the polysaccharide appears to result from the action of specific enzymes each of which *recognizes the structure required for the* addition of the next sugar The possibility remains that the antigenic portions of the molecule whose structure is genetically controlled may be coded by a kind of messenger RNA although evidence for this has not yet been provided

Lipid Synthesis

Lipid synthesis in bacteria problably follows mechanisms similar to those worked out *for mammalian cells although the details* are lacking Bacteria may contain unusual lipids for example, the lipid found in the endotoxin of gram negative microorganisms contains glucosamine rather than glycerol and a predominant fatty acid in the lipid is β hydroxymyristic acid Hydroxy fatty acids are common in bacterial systems and relatively unknown in mammalian cells Their biochemical origin has not been clarified

Biosynthesis of the Cell Wall Mucopeptide and Teichoic Acids

In the case of the muramic acid mucopeptides, which are important structural elements in the cell wall of both gram negative and gram positisve microorganisms little is known of the details of biosynthesis The basic structural unit contains β1 6 acetyl glucosaminyl acetyl muramic acid with peptide chains attached to the carboxyl group in the lactyl residue of the muramic acid component The synthesis of the cell wall mucopeptide is inhibited by penicillin and in penicillin treated cells uridine nucleotide derivatives accumulate which appear to be the precursors of the mucopeptide The steps in the synthesis of cell wall precursor are indicated in Figure 24

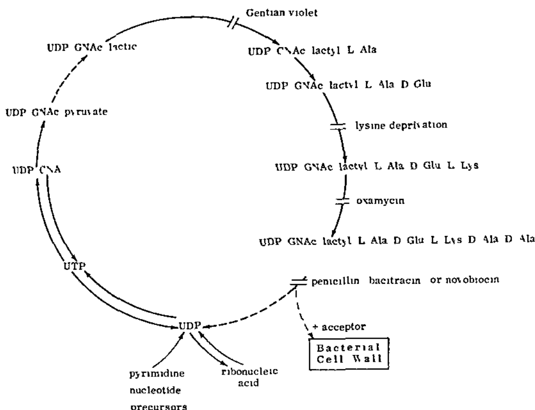

Fig 24 Cycle leading to the synthesis of bacterial cell wall mucopeptide (Strominger J L *in* Gunsalus I C and Stanier R Y (eds) The Bacteria Vol III p 445 New York Academic Press 1962)

The dye gentian violet appears to block the incorporation of the first L alanine residue into the nucleotide In cells treated with oxymycin an analogue of D alanine there appears to be a specific inhibition of the addition of the last D alanyl D alanine group which is attached as a unit rather than as single amino acids Finally the antibiotics penicillin bacitracin and novobiocin appear to block the incorporation of the completed uridine nucleotide derivative into the bacterial cell wall Unfortunately nothing is known of the mechanism of this important step in the process There is reason to believe that new cell wall is synthesized by extension of existing cell wall In lysozyme treated cells where the cell wall has been extensively or entirely removed the synthesis of new cell wall is resumed with great difficulty On the other hand if cell wall synthesis is inhibited by the presence of penicillin in which case the existing cell wall is not destroyed new cell wall synthesis begins as soon as penicillin is removed

Teichoic acid found in the cell wall of gram positive organisms is synthesized by polymerization of ribitol phosphate or glycerol phosphate the precursors are the nucleotides CDP ribitol and CDP glycerol

CONTROL OF METABOLISM

Control of Protein Synthesis

A most striking aspect of bacterial growth is that it responds rapidly to changes in the environment As has been pointed out earlier cells growing in a complex medium containing amino acids and nucleotides will grow and divide more rapidly than cells growing in minimal medium where they are required

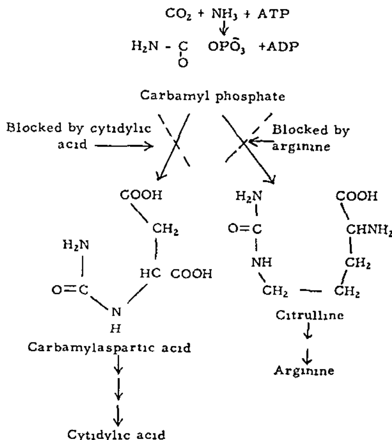

FIG 25 Specific feed back inhibition mechanisms for the control of arginine and pyrimidine synthesis The first step before the branch point is not blocked by either end product

to make all of the components needed for growth It has been demonstrated repeatedly that bacteria tend to make only those enzymes (proteins) which are necessary for growth Cells growing in a mixture rich in amino acids can be shown to lack many if not all of the enzymes required for the biosynthesis of these amino acids Therefore cells growing in a minimal medium must produce many more enzymes than cells growing in a complex medium this probably accounts for the difference in rates of growth under the two conditions

Two mechanisms are known to control protein synthesis in a specific manner One has been termed feedback inhibition and the second enzyme repression In feedback inhibition the product of a biosynthetic pathway specifically *inhibits the first enzyme in* that pathway Thus in the sequence

$$A \longrightarrow B \longrightarrow C \longrightarrow D \longrightarrow \quad X$$

X would specifically inhibit the enzyme responsible for the conversion of A to B An example of this type of feedback inhibition is found in the synthesis of cytidylic acid from aspartic acid The first step in this biosynthetic pathway is the formation of carbamyl aspartate from aspartic acid and carbamyl phosphate a reaction catalyzed by the enzyme *aspartate transcarbamylase* This enzyme is specifically inhibited by the end product cytidylic acid although this substance bears no resemblance to either of the substrates for the enzyme Characteristic of feedback inhibition is that it is generally competitive with the substrate and that it specifically blocks the first step in the biosynthetic pathway Reactions preceding the first specific reaction which may be required for other processes are not affected For example in the biosynthesis of cytidylic acid carbamyl phosphate is a precursor, but car

bamyl phosphate is also required for the biosynthesis of arginine and its synthesis is not inhibited either by arginine or by cytidylic acid (Fig 25)

Enzyme Repression

A second important mechanism for the control of biosynthesis is enzyme repression This mechanism operates at the genetic level and prevents the transfer of genetic information and therefore the appearance of specific enzymes (Fig 26) Specific repressors are formed presumably by way of specific messenger RNA although it is not yet known whether the repressor (R) is RNA or a protein formed in response to a message from RNA The repressor (R) interacts with the effector (F) which would be the end product metabolite or a product formed from the metabolite This yields the modified repressor R which is capable of interacting with the operator portion of the chromosome which controls replication of messenger RNA from the structural genes Thus in salmonella species all of the genes which govern the biosynthesis of histidine are located in one region of the cell this region is controlled by an operator located at one end of the region Interaction of the activated repressor (R′) with the operator prevents the function of the entire portion of the chromosome Since the repressor functions only if histidine is present it must be presumed that there is an interaction between the primary product of the regulator gene and histidine or a metabolite of histidine The same model can be used to account for enzyme induction or the formation of enzyme in response to a specific substrate In this case R acts as a repressor which is neutralized by interaction with the effector

Control of Nucleic Acid Biosynthesis

It is clear from the foregoing that biosynthesis of nucleic acids is itself a controlled process and that only those portions of the bacterial chromosome are active which are required for the growth of the cell under specific conditions For example organisms containing the genes for the metabolism of

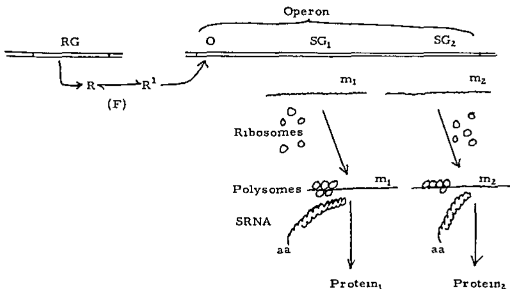

Fig 26 Model of regulation of enzyme synthesis RG regulator gene R repressor converted to R in presence of effector F (inducing or repressing metabolite) O operator SG_1 SG structural genes m_1 m_2 messenger RNAs made by SG_1 and SG aa amino acids attached to SRNA (Jacob F and Monod J On the regulation of gene activity Symposium on Quant Biol 26 193 209 1961)

galactose or galactosides do not possess the enzymes necessary for the utilization of the substrates unless an inducer is present in the growth medium The action of the inducer is considered to be similar to that of the repressor The control gene produces a factor controlling inducibility In the absence of the inducer this product of the repressor prevents the chromosome from expressing it self through the synthesis of the specific messenger RNA This repressor is neutralized by the inducer thus allowing the gene to function and the enzyme to be produced Enzyme induction is characteristic of cata bolic systems while repression is character istic of anabolic systems As a result of the interaction of these mechanisms with the bacterial chromosome the organism is able to cope with rapid changes in its environ ment and to respond to these changes by turning on or turning off the synthesis of specific enzymes, as the requirement of the medium may dictate

Metabolic Control Through Transport or Permeation

Bacteria are able to maintain themselves in an environment whose composition is vastly different from that found inside the cells Generally they can be considered to be quite impermeable to solutes in the medium and to possess selective mechanisms for taking up the substances which they re quire Such specific permeation mech anisms have been described for various carbohydrates amino acids and other deriva tives The permease for galactosides which has been studied extensively is specific for the disaccharide lactose and certain of its analogues It will not effect the transport into the cell of a closely related disaccharide such as maltose Conversely a specific sys tem for the transport of maltose is known which is not active with lactose or other disaccharides A variety of specific permeases have been detected for amino acids In many cases these can be shown to be inducible and to be affected by agents responsible for protein synthesis this evidence suggests that the transport mechanisms are at least in part protein in nature Furthermore they follow the classic kinetics of enzyme systems in cluding competitive inhibition substrate saturation etc Differences in the ability of organisms to utilize various external sub strates may be related to the presence or the absence of specific permeases thus *E coli* is unable to utilize exogenous citrate al though citrate is a normal intermediate in metabolism in this organism On the other hand *Aerobacter aerogenes* can utilize ex ternal citrate The difference has been shown to be due to the presence in *A aerogenes* of a citrate permease This permease is induci ble, it is not formed in cells grown on glucose The presence of specific transport or permeability systems also accounts for differing responses to antibiotics Actinomy cin will inhibit the growth of *Bacillus subtilis* since it can enter the cell and block the synthesis of messenger RNA On the other hand while the synthesis of messenger RNA in *E coli* is just as sensitive as it is in *B subtilis* in the former actinomycin is ex cluded from the cell and therefore the intact cell is resistant to this antibiotic Canavanine is an antibacterial agent in some organisms because it interferes with the utilization of aspartic acid However certain resistant mutants have lost the ability to transport canavanine which appears to be transported by the arginine permease Thus external canavanine is blocked from inter fering with the utilization of endogenous arginine Similar specific and active transport mechanisms must exist for a variety of other cell components such as salts and ions These have been little studied in bacteria

netic information proteins as catalysts and carbohydrates and fats as sources of energy Only comparatively recently has sufficient information accumulated regarding the broad similarities among cells to permit attention to be directed to dissimilarities to the chemical processes which determine that each species of organism is uniquely different from every other Antibiotics have been and will be important tools in such studies

In this chapter we shall examine the mode of action of antibacterial agents from the point of view of the types of reactions in bacteria which are inhibited and the important role which these agents have had in the uncovering and the exploration of these reactions

INHIBITORS OF CELL WALL SYNTHESIS

A remarkable chemical and morphologic difference between bacterial cells and all other types of cells is the presence in bacteria of a rigid outer layer termed the cell wall (see Salton 1960) The cytoplasm of animal plant and bacterial cells is limited by an outer membrane called the cytoplasmic membrane This membrane is relatively fragile and is the permeability barrier of the cell In this membrane are permeases which catalyze the translocation of nutrients and ions in and out of the cell In addition to this membrane bacterial and plant cells are bounded by a more rigid external layer the cell wall Some bacteria also have a third layer the capsule less defined morphologically and external to the cell wall

The cell wall of bacteria is chemically distinct from the walls of fungi and other plants It is an exceedingly complex polymer in

Mechanisms of Action of Antimicrobial Agents

Without question the control of infectious diseases in the last half century albeit still incomplete is the greatest advance ever made in the conquest of human disease This advance is the consequence of the introduction of public health measures of specific immunization technics and of chemotherapeutic agents selectively toxic for bacteria but relatively nontoxic for the infected human host The possibility of finding such selectively toxic antibacterial agents had occurred to Pasteur but in 1906 the German chemist Ehrlich (see Ehrlich and Hata 1910) made the first discovery of such an agent arsphenamine the magic bullet This substance or some closely related compound was employed in the treatment of syphilis for over 30 years

The modern era of chemotherapy was ushered in by the accidental discovery of a powerful bactericidal agent penicillin by Fleming in 1929 (see Fleming 1946) and by the further success of another German chemist Domagk (1935) in discovering a synthetic chemical with a broader antibacterial spectrum than arsphenamine Prontosil * Dubos (1939) then attempted systematically to find in the soil some organism which might excrete substances toxic to other bacteria He did find two such substances tyrocidin and gramicidin which were potent antibacterial agents but which unfortunately were too toxic to be used parenterally in the human host This experience was typical Many screening programs in the past decade have led to the isolation of innumerable antibiotic producing organisms but among the substances found only a few were sufficiently selectively toxic to be used in human beings In the early 1940 s spurred partly by the need for antibacterial agents in World War II Florey and Chain undertook the isolation of penicillin (see Florey 1949) The birth of modern chemotherapy came when this purified substance was injected into experimental animals and found not only to cure infections but also to possess incredibly low toxicity for animals This fact ushered in an intense search for other antibacterial agents of low toxicity and led in rapid succession to the isolation of streptomycin chloramphenicol the tetracyclines and a whole host of other antibiotics

The thread which runs through this brief history is the two words selective toxicity They imply that the biochemical processes of bacteria are in some way different from those of animal cells and that advantage of this difference can be taken in chemotherapy All cells are of course fundamentally similar in their chemical reactions utilizing nucleic acids as the carriers and messengers of ge

* Prontosil is an azo dye and is broken down in the animal organism to p aminobenzene sulfonamide (sulfanilamide) It is the sulfonamide not the dye which is in fact the antibacterial agent

NOTE Data are expressed as specific activities (c p m /mg) DAP = diaminopimelic acid (Nathenson and Strominger 1961)

inhibits wall synthesis (Table 1) The mode of killing of gram negative bacteria by penicillin appears to be fundamentally similar to the mode by which it kills more sensitive gram positive organisms Presumably a difference in the ability of penicillin to penetrate to the site of its action or differences in affinity of the binding site for penicillin account for the relative resistance of gram negative bacteria The new synthetic penicillins and the cephalosporins all appear to inhibit through the same mechanism (Rogers and Jeljaszewics 1961)

In addition to penicillin a number of other antibacterial agents inhibit cell wall synthesis A portion of the cell wall is synthesized by a reaction cycle of the uridine nucleotides (Fig 3) The inhibitors are placed at various points in this cycle with reference to the particular nucleotides which accumulate Thus penicillin bacitracin (Abraham and Newton 1958) ristocetins (Wallas and Strominger

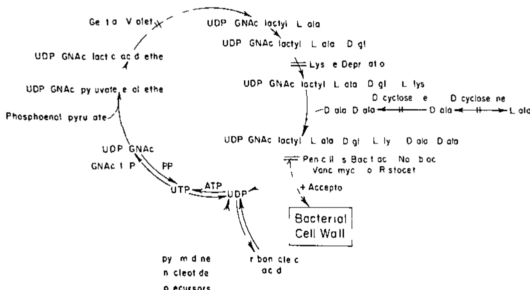

FIG 3 Reaction cycle which leads to the synthesis of part of the cell wall of *Staph aureus* Points of inhibition by various agents are indicated (Modified from Strominger 1962)

variably containing 2 amino sugars (acetyl glucosamine and a lactic acid ether of acetylglucosamine called acetylmuramic acid) and 4 amino acids (D alanine L alanine D glutamic acid and either L lysine or meso α ε-diaminopimelic acid) These are the constituents of the basal layer of the wall a polymer containing a polysaccharide and a highly cross linked peptide (Fig 1) (see Strominger 1962) * The two sugars alternate in the polysaccharide and in *S aureus* are linked by β 1 4 bonds In some species the N acetylmuramic acid residues are also O acetylated i e N O diacetylmuramic acid is present Possibly other differences between species occur in the polysaccharide However the whole structure has not yet been completely elucidated in one species and only scanty data on comparative biochemistry are available Similarly no full study of the cross linked peptide has been published but the available data indicate that there are gross differences in the nature of the cross links among species N acetylmuramic acid is a unique component of bacteria and has been found in no other type of cell Indeed its presence in *Streptomyces* has been used as a basis for classifying these organisms as true bacteria Diaminopimelic acid and the D amino acids are also unusual constitutents of bacterial cells

The cell wall is essential for the integrity of most microbial cells in their normal environment Egg white lysozyme brings about lysis by catalyzing hydrolysis of the cell wall polysaccharide resulting in solubilization of the entire wall However lysis of bacterial cells by egg white lysozyme can be prevented if treatment with the enzyme is carried out in hypertonic broths (Weibull 1953) Under these conditions the cells are converted to spherical forms lacking cell walls and called protoplasts Bacteria have unusually high internal osmotic pressures estimated to be equivalent to 5 to 20 atmospheres due to the fact that they concentrate nutrients against an osmotic gradient The hypertonic solutions are needed to counterbalance this osmotic pressure If protoplasts with their fragile limiting cytoplasmic membranes are placed in media of ordinary tonicity they explode

Penicillin can also induce this evolution of bizarre or spherical forms in bacteria (Duguid 1945 Lederberg 1956) resulting in lysis if the treatment is carried out in ordinary media However in hypertonic broth the spherical forms are stabilized (Lederberg 1956) just as are those which are produced under the action of lysozyme If the penicillin is washed out of the culture these organisms grow and revert to their normal form In one species, growth and cell division occur as a spheroplast in the presence of penicillin (Lark 1958) These observations indicate that penicillin has no deleterious effect and certainly no lethal effect on that portion of the organism internal to the cell wall and they led to the hypothesis that penicillin interferes either with the maintenance or the integrity of the cell wall

Independently of this line of investigation it was found that a uridine nucleotide containing an unusual activated sugar fragment accumulated in *S aureus* after treatment with penicillin (Park 1952 Strominger 1957) The fragment which this nucleotide contained was an acetylmuramyl peptide similar in structure to a part of the cell wall These observations suggested that the accumulated nucleotide was a biosynthetic precursor of the cell wall and therefore led also to the hypothesis that penicillin was a selective inhibitor of bacterial cell wall synthesis there by inducing nucleotide accumulation (Park and Strominger 1957 Strominger *et al* 1959)

Isotopic experiments carried out in a number of laboratories have shown that penicillin does in fact inhibit cell wall synthesis while permitting protein and nucleic acid synthesis for example to go on at normal rates thus demonstrating directly its selectivity as an inhibitor of cell wall synthesis (Gale *et al* 1958 Handock and Park 1958 Mandelstam and Rogers 1959 Nathenson and Strominger 1961) Even in *E coli* which is relatively resistant to penicillin a growth inhibitory concentration of the antibiotic selectively

* In addition to the polysaccharide and the peptide which are components of the glycopeptide all bacteria contain additional wall components referred to as special structure These components are immunologically active in higher animals as for example the teichoic acid of *S aureus* or the group carbohydrate of *S hemolyticus* or the lipo polysaccharide of *E coli*

of wall synthesis need not be its primary mode of action D-cycloserine (Ciak and Hahn, 1959 Strominger *et al* 1959) and gentian violet inhibit at earlier points and lead to the accumulation of earlier precursors

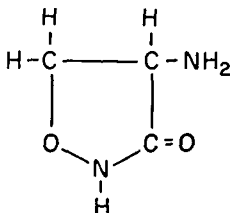
The penultimate reactions in cell wall synthesis those that lead to the utilization of the nucleotide intermediates for polymer (i e cell wall) synthesis are only beginning to be understood and only a few of the reactions which must be involved have been identified It seems unlikely that each of the five antibiotics which inhibits at this penultimate stage does so in precisely the same manner Those five compounds represent several different types of structure and among them only penicillin and bacitracin show cross resistance The most recent information suggests that ristocetins and vancomycin directly inhibit the transfer reaction involving the uridine nucleotide (Anderson and Meadow 1964 Meadow *et al* 1964) The others could interfere with other aspects of polymer synthesis e g synthesis of the acceptor (which the uridine nucleotide transglycosylase requires) with access of substrate to this acceptor with formation of the complex peptide cross bridge or even with the integrity or replication of a cell wall synthesizing particle Studies of models have suggested that penicillin may be an analogue of acetylmuramic acid (Collins and Richmond 1962) but experimental proof of this idea is still lacking

D-cycloserine inhibits at an earlier point in the cycle (Fig 3) leading to the accumulation of a uridine nucleotide which lacks two D alanine residues This antibiotic is a competitive antagonist of the utilization of D alanine for cell wall synthesis In whole cells nucleotide accumulation induced by D-cycloserine is reversed by D alanine In vitro two enzymatic reactions for which D alanine is a substrate are competitively inhibited alanine racemase and D alanyl D alanine synthetase (Strominger *et al* 1960 Neuhaus and Lynch 1964)

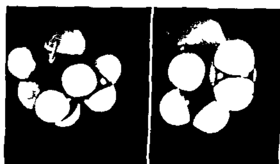
1 L alanine $\rightleftharpoons$ D alanine (alanine racemase)

2 2 D alanine + ATP $\rightarrow$ D alanyl D alanine + ADP + P_i (D alanyl D alanine synthetase)

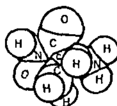
The antibiotic is a structural analogue of the substrate (Fig 4) It is bound to the inhibited enzymes about 100 times as efficiently as their natural substrate D alanine Presumably the ring present in the antibiotic but absent in the substrate fixes the antibiotic in one configuration and by restricting molecular rotation in this manner either makes it relatively difficult for the molecule to come off the enzyme surface or relatively easy for it to go on the enzyme surface One of the enzymes which is inhibited alanine racemase contains pyridoxal phosphate as a coenzyme D-cycloserine is known to react with pyridoxal phosphate in a complex manner and L-cycloserine (which does not inhibit cell wall synthesis) will inhibit some reactions of L alanine involving pyridoxal phosphate enzymes The use of D-cycloserine in chemotherapy is limited by a severe central nervous system toxicity in man This toxicity could be due to a reaction with pyridoxal phosphate in nervous tissue



The large viruses such as meningopneumonitis and psittacosis are inhibited by both cycloserine and penicillin Cycloserine inhibition is reversed by D alanine (Moulder *et al* 1963) These viruses have cell walls containing acetylmuramic acid and they may be defective bacteria rather than true viruses



The discovery that a number of antibacterial agents are selective inhibitors of cell wall synthesis has opened a whole new area of microbial physiology to exploration These substances have provided both the conceptual background and the tools with which to obtain intermediates needed for the study of the structure and the biosynthesis of bacterial cell walls As more information is obtained perhaps it may be possible to design more effective inhibitors of cell wall synthesis or to find other ways of bringing about the death of bacterial cells as a consequence of the loss of integrity of the cell wall



AGENTS THAT AFFECT THE INTEGRITY OR THE FUNCTION OF THE CELL MEMBRANE

D-alanine

FIG 4 Structures (*left*) and molecular models (*right*) of D alanine and D cycloserine (Strominger J L Biosynthesis of bacterial cell walls *in* Gunsalus I C and Stanier R Y (eds) *The Bacteria vol 3 New York Acad Press pp* 413-470)

of wall synthesis need not be its primary mode of action D-cycloserine (Ciak and Hahn 1959 Strominger *et al* 1959) and gentian violet inhibit at earlier points and lead to the accumulation of earlier precursors

The penultimate reactions in cell wall synthesis those that lead to the utilization of the nucleotide intermediates for polymer (i e cell wall) synthesis are only beginning to be understood and only a few of the reactions which must be involved have been identified It seems unlikely that each of the five antibiotics which inhibits at this penultimate stage does so in precisely the same manner Those five compounds represent several different types of structure and among them only penicillin and bacitracin show cross resistance The most recent information suggests that ristocetins and vancomycin directly inhibit the transfer reaction involving the uridine nucleotide (Anderson and Meadow 1964 Meadow *et al* 1964) The others could interfere with other aspects of polymer synthesis e g synthesis of the acceptor (which the uridine nucleotide transglycosylase requires) with access of substrate to this acceptor with formation of the complex peptide cross bridge or even with the integrity or replication of a cell wall synthesizing particle Studies of models have suggested that penicillin may be an analogue of acetylmuramic acid (Collins and Richmond 1962) but experimental proof of this idea is still lacking

D-cycloserine inhibits at an earlier point in the cycle (Fig 3) leading to the accumulation of a uridine nucleotide which lacks two D alanine residues This antibiotic is a competitive antagonist of the utilization of D alanine for cell wall synthesis In whole cells nucleotide accumulation induced by D-cycloserine is reversed by D alanine In vitro two enzymatic reactions for which D alanine is a substrate are competitively inhibited alanine racemase and D alanyl D alanine synthetase (Strominger *et al* 1960 Neuhaus and Lynch 1964)

1 L alanine ⇄ D alanine (alanine racemase)

2 2 D alanine + ATP → D alanyl D alanine + ADP + P_i (D alanyl D alanine synthetase)

The antibiotic is a structural analogue of the substrate (Fig 4) It is bound to the inhibited enzymes about 100 times as efficiently as their natural substrate D alanine Presumably the ring present in the antibiotic but absent in the substrate fixes the antibiotic in one configuration and by restricting molecular rotation in this manner either makes it relatively difficult for the molecule to come off the enzyme surface or relatively easy for it to go on the enzyme surface One of the enzymes which is inhibited alanine racemase contains pyridoxal phosphate as a coenzyme D-cycloserine is known to react with pyridoxal phosphate in a complex manner and L-cycloserine (which does not inhibit cell wall synthesis) will inhibit some reactions of L alanine involving pyridoxal phosphate enzymes The use of D-cycloserine in chemotherapy is limited by a severe central nervous system toxicity in man This toxicity could be due to a reaction with pyridoxal phosphate in nervous tissue

The large viruses such as meningopneumonitis and psittacosis are inhibited by both cycloserine and penicillin Cycloserine inhibition is reversed by D alanine (Moulder *et al* 1963) These viruses have cell walls containing acetylmuramic acid and they may be defective bacteria rather than true viruses

The discovery that a number of antibacterial agents are selective inhibitors of cell wall synthesis has opened a whole new area of microbial physiology to exploration These substances have provided both the conceptual background and the tools with which to obtain intermediates needed for the study of the structure and the biosynthesis of bacterial cell walls As more information is obtained perhaps it may be possible to design more effective inhibitors of cell wall synthesis or to find other ways of bringing about the death of bacterial cells as a consequence of the loss of integrity of the cell wall

AGENTS THAT AFFECT THE INTEGRITY OR THE FUNCTION OF THE CELL MEMBRANE

Although the cell wall is a unique component of the outer surface of cells of plants and bacteria the cytoplasm of *all* living cells is bounded by a limiting cell membrane This

structure is the permeability barrier and has the function of controlling the internal com position of the cell Through it must pass all of the nutrients which are used to form cellu lar compounds and the ions which are con tained in the cellular environment It acts as a selective membrane to organic molecules and to inorganic ions Some organic mole cules are excluded others are concentrated by specific energy dependent mechanisms to which the name permeases has been applied Inorganic ions are also exchanged selectively so that the internal composition of the cell may be quite different from the composition of the extracellular fluid It is not surprising therefore that this important external mem brane is a site of attack for many cytotoxic agents That some of these agents are more toxic for one type of cell than for another reveals another aspect of biochemical individuality among cells and permits some of these agents to be used for chemotherapeutic purposes

The immediate onset of leakage of cellular constituents is the consequence of membrane damage and provides a simple method for measuring the effects of these antibacterial agents which have such an action Depending on the extent of damage ions, small organic molecules such as purine and pyrimidine nucleotides (which absorb at 260 mμ) amino acids and phosphate esters and even larger molecules such as protein may escape from the cell with consequent impairment of a large number of cellular metabolic activi ties The loss of these constituents is most easily followed by the loss of material ab sorbing at 260 mμ

Polypeptide Antibiotics

The cationic detergents (e g Zephiran) are the simplest examples of agents which bring about the death of bacterial cells by disrupting the function of the cell membrane A number of highly toxic polypeptide anti biotics also exert their bactericidal action through this mechanism (Fig 5) These in clude the cyclic polypeptides tyrocidin

Fig 5 Effects of polymyxin on *Pseudomonas aeruginosa* (1) Normal cells (2) Cells treated with 25 μg/ml of polymyxin This concentration causes maximum release of 260 mμ absorbing material from the cells (3) Cell treated with 500 μg/ml of poly myxin (Newton, B A J Gen Microbiol 9 54)

gramicidin polymyxins and colistin (Hotchkiss 1946 Newton 1956 Newton 1958 Chapman 1962) However some selectivity exists in their action since it is apparent that these agents can be used on superficial infections and with great caution parenterally Renal damage is a common toxic consequence but it is apparent that, although the therapeutic margin is narrow massive necrosis of animal cells does not occur at concentrations which may be bactericidal Similarly some microorganisms are not sensitive to the effects of these agents and resistant strains of previously sensitive organisms have been isolated The structure of cell membranes whether in microorganisms or in higher forms of life is virtually unknown and further information about the mechanism by which these agents disorganize the function of cell membranes must await more detailed knowledge of the structure and the function of these membranes

It may be pointed out that inhibition of cell wall synthesis in some cases may be only a special example of limited membrane damage since the cell membrane of bacteria is believed to contain the enzymes necessary for synthesis of the cell wall Although polymyxin is generally considered to disrupt membrane function in a gross manner several observations have suggested that under some circumstances it may have a more limited action on the membrane Thus *Rhodospirillum rubrum* grows as bacilli rather than in the spirillar form at low concentrations of polymyxin and at higher concentrations protoplasts are formed (Tuttle and Gest 1959) In *Neisseria catarrhalis* pretreatment with polymyxin renders the cells sensitive to lysozyme (Warren *et al* 1957) In both cases it may be inferred that polymyxin may be acting in a limited manner on one particular aspect of membrane function synthesis of the cell wall

Polyene Antifungal Antibiotics

A particularly interesting example of the selectivity of some agents for cell membrane damage is the recent demonstration that the polyene antifungal antibiotics disturb the function of the fungal cell membrane Fungi are relatively insensitive to polymyxin and tyrocidin and bacteria are insensitive to the

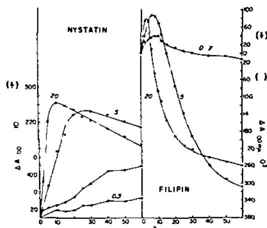

Fig 6 Shrinkage and lysis of protoplasts of *Neurospora crassa* induced by the polyene antibiotics nystatin and filipin Shrinkage (observed as an absorbancy increase) precedes lysis (absorbancy decrease) Lysis occurs more rapidly with filipin than with nystatin (Kinsky S C J Bact *83* 351)

polyene antibiotics The effect of the polyene antibiotics on permeability was observed simultaneously in two different laboratories through two different experimental approaches On the one hand studies of the metabolism of pathogenic yeasts had shown that the polyenes resulted in a severe loss of respiratory metabolism which was eventually traced to the leakage of ions and essential cofactors from the cells into the medium (Marini *et al* 1961) On the other hand studies of *Neurospora crassa* resulted in the finding that mycelial mats obtained from organisms treated with the polyenes had lost considerable weight compared with untreated controls (Kinsky 1961 1964) The weight loss was due to massive loss of intracellular constituents An elegant demonstration of the effect of polyene antibiotics is the measurement of rapid efflux of potassium from *N crassa* accompanied by diminution of the membrane potential recorded with intracellular electrodes (Slayman and Slayman 1962 Slayman 1963 Slayman and Tatum 1964)

These effects of the polyene antibiotics are due to interaction of the antibiotic with a sterol ergosterol which is present in the fungal cell membrane (Kinsky 1962a)

Bacteria do not contain sterols in their cell membranes and hence once more, an aspect of cellular individuality is seen to be the basis of selective toxicity That the lack of effect of polyenes on bacteria is due to the absence of sterols in the membrane rather than to some protective effect of the cell wall is shown by the fact that bacterial protoplasts are also insensitive to these agents By contrast protoplasts of *N crassa* are lysed by the polyenes (Kinsky 1962b) (Fig 6)

The requirement of the presence of membrane sterols for action of polyene antibiotics may also explain some aspects of the toxicity of these agents Hemolytic anemia may be a consequence of therapy with these agents The membranes of red cells contain a sterol cholesterol and red cells are lysed by low concentrations of the polyenes in a manner similar to the lysis of protoplasts of *N crassa* (Kinsky *et al* 1962) The renal toxicity of polyene antibiotics may eventually also be traced to interaction with the sterols which are present in the membranes of animal cells

The function of sterols in membranes is unknown as is an explanation of the ability of bacteria to exist without them Virtually nothing is known about the structure of cell membranes and the statement that the cyclic peptides bring about the disorganization of the lipoprotein of the membrane is simply a restatement of our ignorance of membrane structure This field is certain to be an important and exciting one in the future and the antibiotics which affect membrane function may be important probes in these studies

INHIBITORS OF PROTEIN SYNTHESIS

Chloramphenicol puromycin streptomycin tetracyclines and erythromycin are all believed to act at least in part through inhibition of protein biosynthesis The current (June 1964) concepts of protein biosynthesis outlined here are undergoing almost constant revision

The information for protein sequence is contained in DNA This information is transcribed to messenger RNA (mRNA) through a DNA-dependent RNA polymerase The machinery for transcribing this genetic message from mRNA to protein is the ribosome or an aggregate of ribosomes termed polysomes held together by a strand of mRNA The ribosomes are defined as a class of intracellular particles containing protein and RNA which in the *E coli* system at least sediment in buffered sucrose gradients containing 0 01 *M* $MgCl_2$ with a characteristic velocity and are termed 70s particles At lower Mg^{++} (10^{-4} *M*), each of these particles dissociates into a 30s and a 50s subunit and any mRNA (8-14s) which has been bound is released At still lower Mg^{++} or in the absence of Mg^{++}, further dissociation to particles smaller than 23s occurs The mRNA contains the information for protein biosynthesis in the form of a sequence of nucleotide triplets each triplet (or codon) coding for a particular amino acid Thus 300 nucleotides on an mRNA molecule would contain information for the sequence of a protein of 100 amino acids This sequence of nucleotides must be preceded and followed by periods or commas in the code which signal the beginning or the end of a new protein molecule Perhaps *each* ribosome found in the mRNA polysome complex is concerned with the synthesis of a particular protein coded in one part of the RNA molecule

The amino acids are activated for peptide bond synthesis by the formation of amino acyl sRNA ATP is required for this synthesis and is split in the reaction into AMP and PP Each sRNA molecule is specific for a given amino acid but several different specific sRNA molecules may occur for each amino acid The nonphosphorylated end of all sRNA molecules ends in adenosine and the activated amino acid is esterified to the 3 hydroxyl of the terminal adenosine In addition to components already mentioned two other protein fractions and GTP are required for protein biosynthesis

One present scheme visualizes each ribosome as containing 2 sites for attachment of aminoacyl sRNA on the 50s subunit the initial attachment at site A being determined by the codon of the mRNA molecule in position on the 30s subunit at that moment One supernatant protein factor and GTP would be required for the translocation of this aminoacyl sRNA (perhaps accompanied

by movement of the mRNA molecule along the ribosome) to a second site Then a second sRNA molecule would be bound to the ribosome at the first site and the amino acid at site B now would be transferred from $sRNA_1$ to the free amino group of amino acyl sRNA at site A with formation of dipeptidyl sRNA catalyzed by the second required supernatant protein fraction Thus by repeating this cycle the protein would be synthesized starting from its amino end (which would always remain free) Finally at some comma in the code on the mRNA the protein molecule would be released from the last sRNA molecule (by a mechanism not yet understood) with formation of a soluble protein

Chloramphenicol

In 1953 it was found that chloramphenicol inhibited the incorporation of amino acids into proteins of *S aureus* cells while permitting the synthesis of nucleic acids (Gale and Folkes 1953) In fact both RNA and DNA synthesis proceeded at normal rates (Wisseman *et al* 1954) and under some circumstances RNA synthesis was accelerated (Fig 7) Later it was found that the synthesis of cell wall and a variety of other metabolic processes were unaffected by the antibiotic This striking selectivity of action has provided a remarkable tool with which the processes of nucleic acid synthesis and protein synthesis could be dissociated and has also provided a simple means of distinguishing incorporation of amino acids into cell wall (which is insensitive to chloramphenicol) from incorporation into protein Despite the fact that this substance has been used and studied for over a decade perhaps more extensively than any other antibiotic its precise mode of action remains speculative

In an early observation of considerable importance the accumulation of RNA in the presence of the antibiotic was observed (Wisseman *et al* 1954) This so-called chloramphenicol RNA was believed by many to be an abnormal RNA since after removal of chloramphenicol from inhibited cells it was broken down before cell growth commenced again Its nature has been the subject of extensive investigation and it

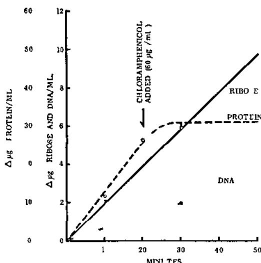

Fig 7 Effect of chloramphenicol on protein RNA and DNA synthesis in *E coli* (Wisseman *et al* J Bact *67* 662)

seems most likely at the present time that it represents a mixture of mRNA and of RNA containing ribosomal particles deficient in protein (Kurland *et al* 1962 Hahn and Wolfe 1961 Midgely and McCarthy 1962 Aronson and Spiegelman 1961) Thus 18s and 25s particles are obtained from chloramphenicol treated cells rather than the 30s and the 50s particles found in normal cells However the RNA obtained from these particles (i e ribosomal RNA) appears to be the same 16s and 23s RNA obtained from normal cells These protein poor ribosomal particles may be precursors of the normal particles and their occurrence may be a secondary reflection of a general depression of protein biosynthesis If indeed mRNA accumulates in chloramphenicol treated cells it is a remarkable fact since the instability or rapid turnover of bacterial mRNA is one of the features which distinguishes protein biosynthesis in bacteria from the same process in animals Recent experiments have suggested that the accumulated RNA is not abnormal since if the treated cells are placed in an enriched medium which permits immediate protein biosynthesis accumulated RNA does not break down (Aronson and Spiegelman 1961)

Chloramphenicol appears to dissociate

FIG 8 Molecular models of chloramphenicol (*left*) and uridylic acid (*right*) (Modified from Jardetzky 1963)

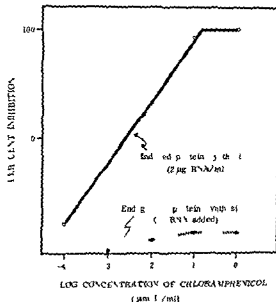

FIG 9 Chloramphenicol inhibition of ribosomal protein synthesis (rabbit reticulocyte system) induced by added mRNA Protein synthesis occurring without added mRNA and due to endogenous mRNA was not significantly inhibited by chloramphenicol In contrast the additional protein synthesis induced by added mRNA was completely inhibited by chloramphenicol (Weisberger A S *et al* *J Exp Med* *120* 161)

RNA synthesis from its normal control Normally RNA synthesis requires concomitant protein synthesis (Gros and Gros 1958 Pardee and Prestidge 1956) For example if an amino acid auxotroph is deprived of its required amino acid RNA synthesis ceases The addition of chloramphenicol under these circumstances has been observed to restore RNA synthesis and under some circumstances the rate of RNA synthesis may be greater than that which occurs normally (Aronson and Spiegelman 1962 Kurland and Maaløe 1962) An explanation of the mechanism of this effect of chloramphenicol is not now available

In cell free systems of bacterial origin chloramphenicol interferes with the incorporation of amino acids into protein However it does not interfere with the activation process i e with the formation of amino acyl sRNA and its locus of action lies somewhere in the complex reaction sequence from amino acyl sRNA to protein on the ribosomal particle (Nathans and Lipmann 1961 Rendi and Ochoa 1962) The best current hypothesis is that this substance prevents attachment of mRNA to ribosomes It has been suggested from nuclear magnetic resonance studies that chloramphenicol is an analogue of uridylic acid (Fig 8) (Jardetzky 1963) and it has been found recently that chloramphenicol inhibits attachment of poly uridylic acid to ribosomes (Jardetzky and Julian 1964) However C^{14}-chloramphenicol is bound to the 50s component of the 70s aggregate (Vasquez, 1964) while the 30s component is the site of attachment of polyuridylic acid and other mRNA molecules These facts remain to be reconciled

If the assumption that chloramphenicol is a uridylic acid analogue is correct this is indeed remarkable since its close chemical relation to phenylalanine and the fact that it inhibited protein synthesis had led earlier to the natural supposition that it was an amino acid analogue Indeed its chemical structure is extremely simple and it is the only antibiotic for which chemical synthesis is preferred to fermentation in commercial production

An explanation of the selective toxicity of chloramphenicol for bacteria as compared with animals (or fungi) is not now available It seems clear that a difference in permeability to chloramphenicol of animal and bacterial cells is not the explanation A cell free protein synthesizing system from rabbit reticulocytes is insensitive to the antibiotic (von

Ehrenstein and Lipmann 1961) and more over chloramphenicol is believed to kill bacteria which are located within animal cells

The basis of selective toxicity may lie in a difference of some detail of the bacterial and the animal protein synthesizing mechanisms The difference in stability or turnover of mRNA previously referred to is the only such difference now known Apparently chloramphenicol is far more effective in inhibiting the protein synthesis stimulated by added mRNA (e g in the form of synthetic polynucleotides) than it is in inhibiting that due to endogenous mRNA already attached to the ribosomes (Fig 9) (Weisberger *et al* 1964a Weisberger and Wolfe 1964) Therefore the difference in sensitivity of animal and bacterial systems to chloramphenicol both in vivo and in vitro could lie in a difference in stability of attachment to or turnover on ribosomes of mRNA Chloramphenicol would thus inhibit only the attachment and the function of new mRNA in bacteria but would have no influence on the function of stably attached mRNA in animal cells

Some data to support this concept have been reported Antibody synthesis must first involve the synthesis and the attachment of new mRNA and it has been observed that formation of antibody in lymph node cultures is strongly inhibited by chloramphenicol (Ambrose and Coons 1963) In treatment of infections in man with chloramphenicol one wonders whether a normal antibody response to infection would occur Similarly chloramphenicol has prolonged skin homograft survival presumably due to inhibition of new antibody synthesis (Weisberger *et al* 1964b) and one wonders whether chloramphenicol might find some use in modification of the immune response Bone marrow cells in tissue culture exhibited a marked reduction in protein synthesis after exposure to chloramphenicol for 4 to 6 days (Djordjevic and Szybalski 1960) Perhaps this time interval is required for displacement of mRNA from the ribosomes or perhaps it reflects the normal slow turnover of mammalian mRNA

Chloramphenicol is a remarkably good agent for the treatment of a number of infections and in some cases appears to be superior to other antibiotics e g in salmonella infections It is unfortunate therefore that toxicity to bone marrow cells which apparently occurs with a very low incidence but high mortality limits its general usefulness (Council on Drugs 1960) This toxicity may be related to the effects on protein synthesis described above although it is difficult at present to describe irreversible marrow aplasia in these terms However it seems likely that immature reticulocytes would be precisely the type of cell which

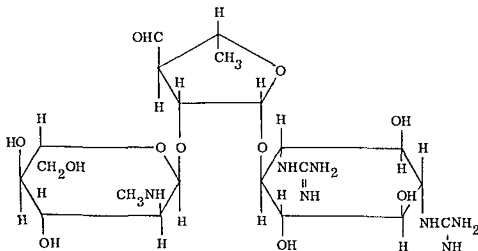

Fig 10 Streptomycin

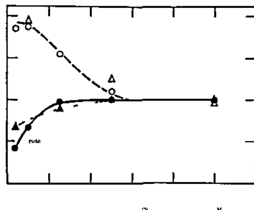

FIG 11 Effect of the streptomycin concentration in the medium on cellular composition of a dependent strain of *E coli* (Spotts C R and Stanier R Y Nature *192* 633)

would be most sensitive to chloramphenicol The maturation of reticulocytes might involve the stimulation of mRNA formation by hormonal or other means thus leading to hemoglobin synthesis as one aspect of maturation It is precisely in this kind of situation the formation of new mRNA and its attachment to ribosomes that chloramphenicol might be expected to have its greatest effect on animal cells

STREPTOMYCIN

The mode of action of streptomycin has been the subject of more controversy in the past few years than has that of any other antibiotic It has been proposed that it (1) induces a permeability defect in bacteria (Anand and Davis 1960) (2) induces synthesis of a specific streptomycin permease (Hurwitz 1964) and (3) is an inhibitor of protein synthesis (Spotts and Stanier 1961) The reader is referred to other reviews for a critical review of these various proposals The effects of streptomycin on protein synthesis will be described here because they appear to be the area of greatest current interest

Streptomycin was discovered as the consequence of a systematic search for new antibiotics soon after the importance of penicillin in chemotherapy became apparent Chemically it is composed of a base streptidine (containing 2 guanido groups) and 2 glycosidically linked sugars streptose and N methyl L glucosamine (Fig 10) Streptose is a branched deoxypentose containing a C formyl group Reduction of the formyl group yields dihydrostreptomycin which has a similar antibacterial spectrum The strongly basic character of these antibiotics is presumably important in their antibacterial activity In early work low potency of some preparations was observed and was due to the presence of an additional fermentation product mannosidostreptomycin Thus the addition of mannose to the streptomycin molecule severely reduces the antibacterial activity

Activity of this group of substances is mainly directed against some gram negative bacteria and mycobacteria but some gram positive organisms are frequently susceptible also So far no one has attempted to explain differences in susceptibility in terms of proposed mechanisms of action

Drug resistance and drug dependence occur rapidly after exposure to streptomycin and have been observed both in vitro and in vivo and any explanation of the mode of action of streptomycin must take account of the fact that resistance dependence and sensitivity appear to be multiple alleles of a single genetic locus Indeed a ribosomal locus of streptomycin action was first proposed on the basis of consideration of these facts (Spotts and Stanier 1961)

Both streptomycin and dihydrostreptomycin have been shown to inhibit protein synthesis including induced enzyme formation (Fitzgerald *et al* 1948) in intact bacteria and amino acid incorporation in reconstructed systems in vitro at extremely low concentrations (Flaks *et al* 1962 Speyer *et al* 1962) In streptomycin dependent bacteria deprivation of streptomycin leads to an increase in the amount of RNA per cell and a decrease in protein and DNA (Fig 11) This phenomenon and the accumulation of RNA in streptomycin sensitive bacteria (Dubin *et al* 1963 Dubin 1964 Stern and Cohen 1964) recall similar phenomena observed in chloramphenicol treated bacteria

As in the case of chloramphenicol streptomycin has no effect on amino acid activation but interferes with the ribosomal phase

of protein synthesis For example the polyuridylic acid stimulated incorporation of phenylalanine is strikingly inhibited (Fig 12) (Flaks *et al* 1962) Streptomycin becomes attached to ribosomes in sensitive cells Although it had been postulated that this attachment would prevent the subsequent attachment of mRNA (Spotts and Stanier 1961) it has been found that mRNA is bound even in the presence of streptomycin The resulting complex is functionally inactive (Davies 1964 Cox *et al* 1964) If mRNA (e g polyuridylic acid) is added to ribosomes before streptomycin the effect of the antibiotic is greatly reduced Incorporation due to endogenous mRNA is also not affected (Fig 12) As indicated above streptomycin is a polyanion and it may attach in the same manner or in place of Mg^{++} or polyamines Streptomycin will bind tightly to several acidic proteins (Brock 1964) as well as to polynucleotides (Cohen 1946) and either an acidic ribosomal protein or ribosomal RNA could be the site of its attachment

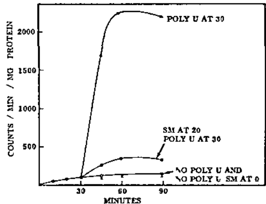

FIG 12 Effect of streptomycin (SM) on polyuridylic acid (poly U) stimulated incorporation of phenylalanine and/or incorporation due to endogenous mRNA (no poly U added) (Flaks J G *et al* Biochem Biophys Res Comm *7* 385)

The site of streptomycin resistance is the 30s ribosome (Davies 1964 Cox *et al* 1964) Ribosomes (70s) from sensitive and resistant cells were each dissociated into 30s and 50s subunits in low Mg^{++} and then 70s ribosomes were reconstituted using various combinations of 30s and 50s ribosomes from the sensitive and the resistant cells A 70s ribosome containing a 30s subunit from a resistant cell was always resistant to streptomycin while sensitivity or resistance was indifferent to the origin of the 50s subunit Thus the 70s ribosome composed of 30s (sensitive) plus 50s (resistant) subunits was sensitive to streptomycin while the ribosome composed of 30s (resistant) plus 50s (sensitive) subunits was resistant The 30s subunit of ribosomes obtained from streptomycin-dependent strains was similarly resistant to inhibition by the drug but no dependence of these ribosomes on streptomycin could be demonstrated (Cox *et al* 1964) However it seems likely that streptomycin would have become tightly attached to these ribosomes during growth in the presence of the drug

The 30s subunit is the site of attachment of mRNA It has not been directly shown that streptomycin is bound to this subunit nor has the competition for binding between streptomycin and chloramphenicol been studied However it will be recalled that the 50s subunit is the site of chloramphenicol binding

It is apparent therefore that streptomycin interferes not with the attachment but with the function of mRNA Even more remarkable is the fact that this functional impairment can be manifested as miscoding (Davies *et al* 1964) Thus in the polyuridylic acid stimulated synthesis of phenylalanine addition of streptomycin can lead to the incorporation of isoleucine Indeed variation of Mg^{++} concentration can also lead to isoleucine incorporation in the absence of streptomycin although to a lesser extent Once again these observations suggest a resemblance between streptomycin binding and Mg^{++} binding Other aminoglycoside antibiotics (kannamycin neomycins B and C) have effects similar to streptomycin but remarkably they alter the code words in different ways leading to stimulation of incorporation of other amino acids Evidence from mutants suggests that kannamycin is bound to ribosomes differently from streptomycin (Tanaka *et al* 1964) Although ribosomes from a streptomycin resistant mutant were resistant to streptomycin

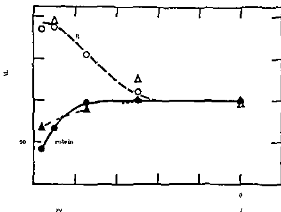

FIG 11 Effect of the streptomycin concentration in the medium on cellular composition of a dependent strain of *E coli* (Spotts C R and Stanier R Y Nature *192* 633)

would be most sensitive to chloramphenicol The maturation of reticulocytes might involve the stimulation of mRNA formation by hormonal or other means thus leading to hemoglobin synthesis as one aspect of maturation It is precisely in this kind of situation the formation of new mRNA and its attachment to ribosomes that chloramphenicol might be expected to have its greatest effect on animal cells

STREPTOMYCIN

Activity of this group of substances is mainly directed against some gram negative bacteria and mycobacteria but some gram positive organisms are frequently susceptible also So far no one has attempted to explain differences in susceptibility in terms of proposed mechanisms of action

Drug resistance and drug dependence occur rapidly after exposure to streptomycin and have been observed both in vitro and in vivo and any explanation of the mode of action of streptomycin must take account of the fact that resistance dependence and sensitivity appear to be multiple alleles of a single genetic locus Indeed a ribosomal locus of streptomycin action was first proposed on the basis of consideration of these facts (Spotts and Stanier 1961)

Both streptomycin and dihydrostreptomycin have been shown to inhibit protein synthesis including induced enzyme formation (Fitzgerald *et al* 1948) in intact bacteria and amino acid incorporation in reconstructed systems in vitro at extremely low concentrations (Flaks *et al* 1962 Speyer *et al* 1962) In streptomycin-dependent bacteria deprivation of streptomycin leads to an increase in the amount of RNA per cell and a decrease in protein and DNA (Fig 11) This phenomenon and the accumulation of RNA in streptomycin sensitive bacteria (Dubin *et al* 1963 Dubin 1964 Stern and Cohen 1964) recall similar phenomena observed in chloramphenicol treated bacteria

As in the case of chloramphenicol streptomycin has no effect on amino acid activation but interferes with the ribosomal phase

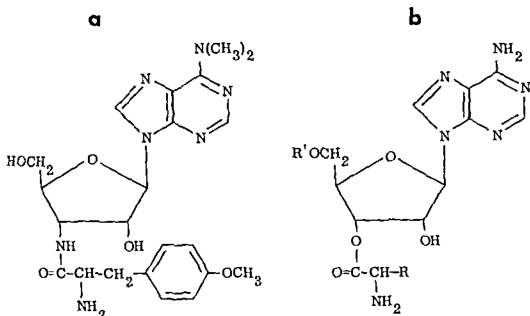

Fig 13 Structures of puromycin (a) and the adenosine end group of aminoacyl sRNA (b) R^1 = phosphodiester to the test of the RNA molecule

carried out Thus puromycin appears to be acting as a metabolic analogue of sRNA of which it is also a structural analogue replacing an incoming amino acyl sRNA molecule in the chain elongation reaction of protein or polypeptide synthesis (Fig 14) Since it is an analogue of only the end of the sRNA molecule it does not attach to the sRNA site on the 50s subunit of the ribosome Hence the polypeptide chain transferred to puromycin is released If puromycin is added during the course of protein synthesis small peptides of various sizes containing the antibiotic are released In the case of the polyuridylic acid stimulated polypeptide synthesis polyphenylalanyl sRNA is formed Since the mRNA employed (polyuridylic acid) contains no signal for the release of polypeptide from sRNA the polyphenylalanyl sRNA remains attached to the ribosome and the subsequent addition of puromycin brings about its release (Gilbert 1963) Thus in this isolated system the puromycin reaction can be used as a model of the peptide bond forming step itself It is noteworthy that this reaction is stimulated by GTP and one of the soluble protein fractions possibly the peptide bond forming enzyme (Traut and Monro 1964) Moreover this step is inhibited by chlortetracycline (see below) and chloramphenicol Whether this effect of chloramphenicol is significant or related to its other known effects remains to be investigated

It is noteworthy that puromycin does not act specifically as an analogue of tyrosinyl sRNA Differences in the actions of various synthetic analogues in which O methyl tryosine is replaced by other amino acids still remain to be explained (Nathans and Neidle 1963) Some analogues e g the glycyl analogue are relatively inactive and an aromatic amino acid appears to be important in obtaining maximum effects The transfer of the amino acid peptide linkage to the 2 or the 5 position of the ribose in the nucleoside destroys activity This structural specificity is the best evidence albeit weak that the amino acid ester is actually located on the 3 position of the ribose in the terminal nucleoside of a normal sRNA

they were sensitive to kannamycin However ribosomes from kannamycin resistant cells were resistant to both antibiotics

This phenomenon may prove to be of much use in further elucidating the ribosomal mechanism Miscoding could provide an explanation of the suppression of various mutations by streptomycin (Gorini and Kataja 1964 Lederberg *et al* 1964) Moreover suppression of a lethal mutation would be an excellent explanation of streptomycin dependence This phenomenon may also provide an explanation of the bactericidal effect of this antibiotic (Davies *et al* 1964) If the formation of abnormal and functionally inactive proteins is induced the presence of these materials could seriously interfere with the ability of the cell to survive, even in the resting state The requirement for a small amount of growth for initiation of the lethal effect of streptomycin could be explained by the fact that streptomycin can be attached to ribosomes only in the absence of mRNA Thus a single cycle of protein synthesis would release mRNA and make the ribosome accessible to the antibiotic

Finally it should be mentioned that chloramphenicol is bacteriostatic and its action is readily reversed Moreover chloramphenicol antagonizes the lethal effect of streptomycin This could be explained by a competition for binding sites or conceivably by the fact that a lethal synthesis i e the synthesis of abnormal proteins is required for killing by streptomycin, while chloramphenicol blocks this lethal synthesis in the same manner as it blocks normal protein synthesis As in the case of chloramphenicol the extreme resistance of animal cells and fungi to the action of streptomycin has not been explained adequately nor is there any explanation of the high toxicity of the amino glycoside antibiotics for the acoustic nerve of higher animals

The means of reconciliation of the observed effects of streptomycin on permeability and on protein synthesis is not immediately apparent However two possibilities suggest themselves If the ribosomal system were closely associated with the membrane both phenomena might be the consequence of binding Alternatively, if streptomycin competes for Mg^{++} or polyamine sites on the ribosome it might also compete for functionally important anionic binding sites on the membrane, perhaps Mg^{++} or Ca^{++} binding sites

Puromycin

This antibiotic is nephrotoxic in animals and is inhibitory to tissue culture cells It is not useful in the therapy of bacterial infections but related compounds have been of some interest as possible anticancer agents Although it had been observed earlier that it inhibited induced enzyme synthesis (Creaser 1955) its unusual structure first suggested that it might function as a specific inhibitor of protein synthesis It is a nucleoside in which the base is 6-dimethylamino purine (6 dimethyl adenine) and the pentose is 3 amino D ribose Moreover the amino group of the sugar is substituted in a peptide linkage with 3 O methyl L tyrosine (Fig 13) This structure suggested that this substance might act as an analogue of amino acyl sRNA (Yarmolinsky and de la Haba 1959) (Fig 13) It was found to inhibit protein synthesis in vitro It did not inhibit the formation of amino acyl sRNA but like chloramphenicol and streptomycin it blocked the ribosomal stage of protein biosynthesis (Yarmolinsky and de la Haba 1959) As the consequence small peptides accumulated in the medium (Nathans *et al* 1962) Moreover nascent protein attached to ribosomes could be released by puromycin (Morris and Schweet 1961) and with the rabbit reticulocyte ribosome system which synthesizes polypeptide chains of hemoglobin containing N terminal valine amino acid labeled puromycin was incorporated into the peptide products in an amount equivalent to the amount of N terminal valine (Allen and Zamecnik 1962) Recently, further evidence that puromycin is a part of the peptide product in the *E coli* system has also been obtained (Nathans 1964a b) Chloramphenicol acts at an earlier point in the ribosomal mechanism than does puromycin since in the presence of both antibiotics no formation of peptides characteristic of the puromycin effect can be demonstrated Analogous experiments with streptomycin have not been

RNA polymerase and DNA polymerase see different surfaces of the DNA molecule At higher concentrations of actinomycin DNA polymerase is also inhibited At these concentrations the melting curve of DNA is shifted upward (Fig 16) Apparently the double stranded configuration is stabilized and lowered activity of the enzyme is due to failure of strand separation of its DNA substrate (Reich 1964)

FIG 15 Model of actinomycin binding to deoxyguanosine of DNA in the B configuration Hydrogen bonds between actinomycin and DNA are indicated by — — and hydrogen bonds between guanine and cytosine in DNA are indicated by (Hamilton L D *et al* Nature *198* 538)

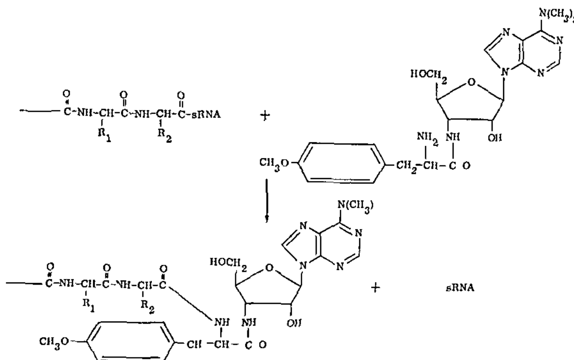

FIG 14 Proposed reaction of puromycin with ribosomal bound polypeptidyl sRNA

Other Inhibitors of Protein Biosynthesis

Tetracyclines (Gale and Folkes 1953 Rendi and Ochoa 1961 Hash *et al* 1964) erythromycin (one of a group of macrolide antibiotics) (Benigno *et al* 1954 Wolfe and Hahn 1964) streptogramin (Vazquez 1962) and lincomycin (Josten and Allen 1964) all have been reported to inhibit protein synthesis in a relatively specific manner Insufficient information is available at present to describe their mechanisms of action in detail The first two of these substances are remarkably nontoxic for animals

INHIBITORS OF NUCLEIC ACID SYNTHESIS

Actinomycin C_1

The actinomycins are bright red peptide containing antibiotics They are highly toxic for animal cells as well as for bacteria and have a useful role in therapy of some tumors They inhibit the growth of DNA viruses but not of most RNA containing viruses Their primary action is due to complex formation with DNA They do not bind to RNA The DNA actinomycin complex is strikingly inhibitory to the DNA dependent RNA polymerase but DNA polymerase is inhibited only at high concentrations of the antibiotic (Reich 1964 Goldberg and Reich 1964)

The actinomycin molecule binds to the deoxyguanosine residues in DNA Binding is readily observed as a spectral shift in the actinomycin chromophore Apurinic DNA and deoxyadenosine thymidine copolymer do not bind the antibiotic However a crab DNA which contains only 2 per cent deoxyguanosine does bind actinomycin The chromophore amino group the quinoidal ring system and the peptide chain lactone ring are all essential for the interaction An elegant model for the binding has been proposed (Hamilton *et al* 1963) (Fig 15)

DNA dependent RNA polymerase is inhibited by low concentrations of the antibiotic (Fig 16) At these concentrations DNA replication is unaffected Apparently

respiratory chain or in the phosphorylating mechanism They have permitted the isolation of portions of the respiratory chain for study and have been utilized in the preparation of fragments of the phosphorylating particles Moreover in several cases the identification of partial reactions as bona fide portions of the mechanism has been aided by their sensitivity to an antibiotic known to inhibit the intact system In addition to those already studied in detail other toxic antibiotics are known to inhibit these systems and it is to be hoped that detailed studies of their mechanisms will shed additional light on this important area of biochemistry The known differences between oxidative phosphorylation in bacteria and in animals also suggests that an antibiotic which inhibits bacterial oxidative phosphorylation and is nontoxic for animals may be found someday

METABOLITE ANALOGUES

Sulfonamides and p Aminosalicylic Acid

The modern history of studies of the mechanisms of killing of bacteria by drugs began with investigations of sulfonamides These early studies led to the discovery by Woods in 1939 1940 even before penicillin had been isolated of a naturally occurring competitive antagonist of sulfonamide action (Woods 1940) This compound was isolated and identified as p-aminobenzoic acid a previously unknown metabolite (Fig 17) Later it was found that p aminobenzoic acid was an essential part of an important coenzyme folic acid The sole metabolic function of p aminobenzoic acid is its role as a folic acid precursor Animals are unable to synthesize folic acid and depend on an exogenous source while bacteria manufacture their own folate compounds Hence only bacteria can be inhibited by sulfonamides Some bacteria do not synthesize folic acid but require it for growth These organisms like animal cells are not inhibited by the sulfonamides

More than 20 years elapsed after this discovery until more detailed knowledge of the structure and the mode of synthesis of folic acid permitted a precise definition of the inhibitory action (Brown 1962) Folate compounds are formed from pteridine precursors The immediate reaction in which p-aminobenzoic acid participates in the ATP dependent condensation of 2 amino 4 hydroxy 6 hydroxymethyl pteridine with p aminobenzoic acid to yield dihydropteroic acid which is subsequently converted to dihydrofolic acid It is this reaction which is inhibited by sulfonamides In fact sulfonamides participate as substrates so that nonfunctional analogues of dihydropteroic acid are formed These products may themselves be inhibitory and kinetics typical of pure competitive inhibition were not obtained

Another analogue of p aminobenzoic acid p-aminosalicylic acid (Fig 17) is an impor

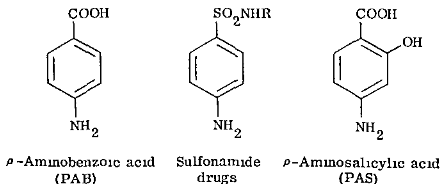

Fig 17 p Aminobenzoic acid (*left*) a sulfonamide (*middle*) and p aminosalicylic acid (*right*)

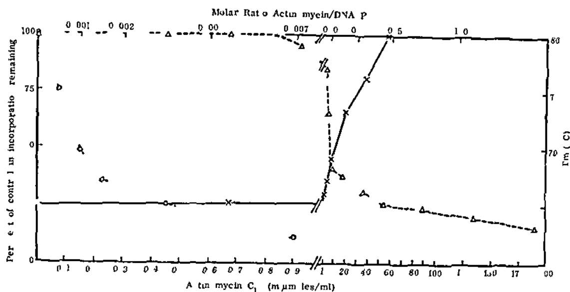

FIG 16 Effect of actinomycin on RNA polymerase (open circles) DNA polymerase (open triangles) and melting curve (T_m) of pneumococcal DNA (crosses) The incorporation of nucleotide in both polymerase reactions is plotted as a function of actinomycin concentration (lower abscissa) while the T_m is plotted as a function of the ratio of actinomycin to DNA P (upper abscissa) The latter ratios correspond to those in the enzyme reaction mixtures (Reich E *Science 143* 684)

MITOMYCIN

This antibiotic is also toxic to both animal cells and bacteria It is an effective antitumor agent and is mutagenic It brings about depolymerization of DNA The substance itself is inactive but on reduction enzymatically or chemically an active form is produced This activated substance is a bifunctional alkylating agent and brings about the cross linking of DNA strands apparently involving deoxyguanosine and deoxycytosine residues on complementary strands (Iyer and Szybalski 1963 Iyer and Szybalski 1964)

OTHER AGENTS

Phleomycin (Tanaka *et al* 1963 Falaschi and Kornberg 1964) a nitrofuran derivative (Endo *et al* 1963) phenethyl alcohol (Berrah and Konetzka 1962) and ethidium bromide (Newton 1957 Elliott 1963) are all inhibitors of DNA and/or RNA synthesis Their mechanisms of action are being studied in a number of laboratories Phleomycin like actinomycin is bound to DNA resulting in an alteration of the melting curve The binding probably involves deoxyadenosine or thymidine residues While the binding of this antibiotic inhibits DNA polymerase the DNA-dependent RNA polymerase is not affected (Falaschi and Kornberg 1964) This situation is just the opposite of that seen with actinomycin C_1

INHIBITORS OF OXIDATIVE *PHOSPHORYLATION*

A number of antibiotics highly toxic for both animals and bacteria, have been found to be inhibitors of oxidative phosphorylation Although studies of the mechanism of oxidative phosphorylation have shown that there are important differences between the bacterial and the animal systems no inhibitors of this kind have been found so far which are selectively toxic for bacteria However those agents which have been found have been extremely useful in studies of oxidative phosphorylation especially antimycin A oligomycin aurovertin and gramicidin (Hotchkiss 1944 Brodie and Gray 1956 Chance 1956 Lardy *et al* 1958 Lardy 1961) These inhibitors act at specific loci in the

peutic agents now used and of the basis of their toxic side-effects in animals Perhaps it will even lead to the design of more effective chemotherapeutic agents than those now available but without question such studies have contributed and will contribute in an important way to that fund of basic knowledge on which modern science including medicine is based

tant antitubercular drug It is remarkable that while *Mycobacterium tuberculosis* is effectively inhibited by p aminosalicylic acid sulfonamides have no inhibitory action Correspondingly sulfonamide sensitive bacteria are by and large insensitive to p aminosalicylic acid Like sulfonamides, p aminosalicylic acid may also be utilized by sensitive organisms in vivo at least to form folic acid analogues

These observations imply that the receptor site for p aminobenzoic acid on the sensitive enzyme may be different in different organisms in one case being fit by sulfonamides and in another by p aminosalicylic acid Indeed alterations in enzyme receptor sites for p aminobenzoic acid are one mechanism by which cells of *E coli* become sulfonamide resistant (Pato and Brown 1963) In view of the importance of p-aminosalicylic acid as an antitubercular drug and the high frequency with which resistance to it develops it is surprising that this system has barely been studied in mycobacteria It may be hoped that the description of the enzymatic mechanisms involved will stimulate further work in this area

The discovery of the p aminobenzoic acid sulfonamide antagonism led to the general concept of antimetabolites as potential therapeutic agents and to the hope that this concept would permit the rational design of new antibacterial substances Although a large number of compounds of various types have been made and tested none of them has possessed the selectivity required for this purpose *

Other Substances

A number of other antibiotics are antimetabolites Thus diazo-oxo norleucine (DON) and azaserine are glutamine analogues (Hartman *et al*, 1956) and hadacidin is an L aspartic acid analogue (Shigeura and Gordon 1962) Psicofuranine is an adenosine analogue, containing the keto sugar psicose rather than ribose This latter is of particular interest because it illustrates a novel mechanism of antimetabolite action (Moyed 1961) The antibiotic is an inhibitor of xanthosine 5 phosphate aminase which catalyzes the formation of guanylic acid XMP + ATP + $NH_3 \rightleftarrows$ GMP + AMP + PP This enzyme has an allosteric regulatory site for which AMP may be the normal regulator The antibiotic appears to inhibit the enzyme by acting at the regulator site Several synthetic amino acid analogues have a similar action in inhibiting amino acid biosynthesis

* A striking exception to this statement in another area of chemotherapy is iododeoxyuridine This compound was originally synthesized as a nucleic acid antimetabolite in a search for anticancer agents and does have limited use in the therapy of some tumors However it is a potent inhibitor of the replication of *Herpes simplex* a DNA-containing virus Infection of the eye with *Herpes* is an important cause of blindness and local instillation of iododeoxyuridine in the eye produces a rapid cure of this disease (Kauffman *et al* 1962) This compound is the first antiviral agent of value It is also being tried in the treatment of smallpox

CONCLUSION

In concluding a chapter on the mechanism of action of antimicrobial agents one pauses to reflect on the enormous effort which has been expended in this area of investigation This has been due largely to the fascination of scientists with antibiotics as keys with which to unlock new areas of microbial physiology These efforts have been richly rewarded Studies of sulfonamides led to the isolation of p aminobenzoic acid and studies of penicillin led to the full realization of the functional importance of the bacterial cell wall Chloramphenicol and other antibiotics have been exceedingly important in unravelling the mysteries of protein and nucleic acid synthesis and perhaps the polyenes and other antibiotics will play a similar role in the eventual understanding of membrane structure and function It is of interest that most of the agents studied have interfered in one way or another with the macromolecular components of bacterial cells and that simple competitive antagonism is a relatively unusual phenomenon The concept of biochemical individuality among cells is slowly being defined partly with the aid of these substances and indeed is the basis of the selective toxicity of those antibiotics which are useful in chemotherapy It is to be hoped that these fundamental investigations will lead to a better understanding of the thera

Pathogenic Properties of Bacteria

INTRODUCTION

Our purpose in this chapter is to discuss examples of factors possessed by bacteria that enable them to cause disease Much has been written about commensalism and parasitism between microorganism and animal or plant host It has been stressed that disease is a rare event in the normal parasitic relationship and therefore is a minor aspect of parasitism in which peaceful coexistence is averred to be the rule On the other hand depression of the host s resistance by ionizing radiations for example shows clearly that bacteria which we are wont to consider as commensals, the normal flora of the gut under usual circumstances are prevented from invading the tissues to cause disease and death only because the protective mechanisms are intact Furthermore many of the species of microorganisms that cause disease are not found in a benign parasitic relationship as for instance the viruses of influenza measles and smallpox in man or rinderpest in cattle When these agents have been introduced into a population overt disease is the rule unless specific prophylaxis by immunization has been practiced or the population has become immune because of previous epidemic infection Between the two extremes of parasites which usually are commensal and those that usually cause widespread disease in the unimmunized there is a spectrum of relationships in which the frequency of disease depends on an unsteady balance between the state of the host and the pathogenicity of the numberless microbial species or strains that are encountered

From the standpoint of the host the aim is to preserve homeostasis and a variety of protective mechanisms are available to achieve this end Homeostasis can be maintained despite the presence of large and varied microbial populations provided that they are restricted to certain regions of the body where they can be tolerated However, if for one reason or another there is a defect in the homeostatic barriers and the microorganisms gain access to other tissues disease results The relation betwen microbe and host is dynamic whether the species of microorganism is classed as pathogen or commensal The host appears to do everything in its power to rid itself of the parasite and if this is not possible at least to restrict it to a region where it can do the smallest amount of harm or occasionally be of benefit because the parasite is uniquely able to synthesize nutritional factors necessary for the host or possesses enzymes capable of cleaving ingested materials to a state in which the host can utilize them

In summary it can be said of the relations between host and microorganism that in some instances there is a state of relatively peaceful coexistence or commensalism in others there is an uneasy truce that is commonly broken and in the case of highly pathogenic microbial species the usual state is open warfare Whatever military figure of speech is used to describe the complex relationships

it is clear that no single generalization can apply to all but that each case needs to be analyzed separately as has been done in subsequent chapters

PATHOGENIC PROPERTIES OF BACTERIA

The term *pathogenicity* refers to the capacity of microorganisms to cause disease either natural or experimental in a given host species Pneumococcus is pathogenic for the mouse although spontaneous pneumococcal disease never has been observed in this species Nonetheless the mouse is extremely susceptible to experimental infection and rapidly succumbs following injection of only a few bacteria In order for disease to occur naturally in a population pathogenic bacteria must be endowed also with certain attributes which will be discussed under the collective term *communicability* although it should be borne in mind that factors pertaining to the host or to intermediate vectors in addition to intrinsic properties of the microbes play a large part in transmission of infection from one individual to another

Pathogenicity and virulence have commonly been used as synonyms but as Miles (1955) has pointed out a useful distinction can be made between the terms Pathogenicity may be regarded as a general attribute of a species or genus or some other grouping of microorganisms the term *virulence* being used to indicate the degree of pathogenicity of a given type strain or clone as observed in a particular host species under defined conditions *Bacillus anthracis* is pathogenic for many genera of animals Mutant strains or variants of anthrax bacillus show great differences in virulence or relative pathogenicity when tested in guinea pigs for example and the differences in virulence are stable characteristics of the variants These then are virulent or avirulent strains of the pathogenic species *B anthracis* Pathogenicity of pneumococcus as a species is attributable to the presence of antiphagocytic polysaccharide capsules which surround the cells In the same animal species mouse enormous differences in virulence occur as characteristics of different capsular types Moreover within a single type stable mutants exhibit high or low virulence correlated with synthesis of large or small amounts respectively of capsular polysaccharide

Although the virulence of a specified stable strain of a microbial species can be measured with relative reproducibility in a given inbred strain of laboratory animal it is common place to find quite different results when other strains of the same animal species are similarly tested It follows that the results found in one animal species should not be extrapolated to another

Virulence can be expressed only in comparative terms because of variations in both host and parasite To arrive at even a rough numerical value for the virulence of a newly isolated microorganism be it bacterial viral or fungal requires the use of large numbers of animals infected with increments of dosage and whenever possible by comparison with the results found with a calibrated strain of the same species tested at the same time Then a numerical comparison of virulence for the animal species under test can be made based either on the number or the dose of infectious agents required to produce a pathologic effect or else by differences in the effect caused by similar doses of each microbe

The nature of the effect chosen as the indicator of virulence may vary from the number of microorganisms or colony producing units found per unit weight of a selected infected tissue to an estimate of the number and the extent of the lesions produced Death of the animal usually provides the most secure end point

The concept of a minimum lethal dose (M L D) of microorganisms as a measure of virulence may be grossly misleading because it does not take account of variations in resistance of different members of the host population of variation in virulence among the microorganisms inoculated nor of differences in response to increments of dose Death rates resulting from constant increments of dose in similar groups of a population of animals are found usually to increase slowly in the range of 1 to 10 per cent and 90 to 99 per cent mortality and most rapidly in the region of 50 per cent mortality For this reason the dose that kills

50 per cent of the animals can be estimated more precisely than at either extreme of the mortality curve As a result the median or 50 per cent lethal dose (LD_{50}) is used most commonly in the description of virulence Calculation of the LD_{50} can be made by employing a formula such as that devised by Reed and Muench (1938)

In infectious processes where death can not be used as the endpoint, other pathologic effects can be related to the dosage of microbes required to produce them in 50 per cent of the test animals in a given time This dosage is often referred to as the median or 50 per cent infectious dose (ID_{50})

Although estimation of the median lethal dose of certain well studied strains of microbes can be made in the laboratory with fair reproducibility it should be emphasized that this measurement may bear little relation to virulence of a species of bacterium in the natural state

MICROBIAL FACTORS THAT DETERMINE PATHOGENICITY

The production of disease involves interaction between microbe and host and for this reason discussion of the pathogenic properties of the infective agent requires also a consideration of factors of host resistance Recognition that bacterial products are concerned in virulence depends on the specific pathologic effects they produce as well as on the immunologic response of the host to the infective agent or fractions of it

Bail and Weil (1911) introduced the word aggressins to describe nontoxic factors produced by *B anthracis* and other bacteria that interfere with host resistance and cause the production of specific, protective antibodies The usefulness of the term is debatable The same may be said for the expression aggressive factors which have been defined as substances produced by microorganisms that assist them to establish or extend the infection by inhibiting phagocytosis by breaking down mechanical barriers to spread or by killing the host s tissues The expression aggressive factors is so comprehensive that it could almost be used as a synonym for pathogenic factors However because of the confusion that might result the terms pathogenic factors or virulence factors will be used in the present discussion

It should be understood clearly that the factors which govern the pathogenicity of one bacterial species may be entirely different from those of another species This may be illustrated by contrasting the factors concerned in the pathogenicity of *Clostridium tetani* and pneumococcus

If the spores of *Cl tetani* are introduced into a wound together with some material capable of causing local tissue damage germination takes place, and growth of the vegetative form of the bacillus occurs locally During growth a highly poisonous and freely diffusible protein tetanus toxin is elaborated by the bacteria The toxin travels centripetally along peripheral nerves probably in the interneuronal tissue spaces (see Wright 1955) reaches the central nervous system where it affects the motor neurons and produces the frequently fatal disease tetanus The bacteria themselves are present only at the original site of introduction All the characteristics of the natural disease can be reproduced in animals by injecting minute doses of highly purified tetanus toxin, immunization by means of toxoid prepared from the toxin prevents the disease *Cl tetani* possesses a single factor tetanus toxin which appears to account for its pathogenic qualities

The course of events differs greatly when a few virulent pneumococci are introduced into the tissues of a susceptible animal The microorganisms multiply rapidly invade the blood stream and are carried throughout the body At death they are found in large numbers in all organs in striking contrast with the animal infected with tetanus bacilli The capacity to invade and multiply in the tissues is determined by the polysaccharide capsule which surrounds virulent pneumococci This viscous substance inhibits ingestion of the microbes by phagocytes apparently in a mechanical way and is not toxic for the isolated phagocytes or for the intact animal even though injected in very large amounts No toxin in any way analogous to tetanus toxin is known to be produced by pneumococcus Furthermore antibodies to the purified polysaccharides confer complete protection against infection

Therefore the single demonstrable patho

TABLE 1 FACTORS THAT INFLUENCE PATHOGENICITY OF SOME BACTERIAL SPECIES

BACTERIAL SPECIES	NATURE	SITE OF ACTION	MODE OF ACTION	SPECIFIC IMMUNITY TO INFECTION	COMMENT
Pneumococcus	Capsular polysaccharide	*Phagocytes*	Inhibits phagocytosis	Antipolysaccharide antibodies	Antibodies enhance phagocytosis No significant toxin identified
Hemophilus influen ae	Capsular polysaccharide	Phagocytes	Inhibits phagocytosis	Antipolysaccharide antibodies	Role of endotoxic factors unknown
Streptococcus pyogenes	M proteins at cell surface	Phagocytes	Inhibits phagocytosis	Anti M protein antibodies	Hyaluronic acid is not antigenic Antibodies to various toxins do not prevent infection but may mitigate it, e g antierythrogenic toxin prevents rash of scarlet fever antistreptokinase inhibits digestion of fibrin by streptokinase plasminogen plasmin system
	Hyaluronic acid capsule	Phagocytes	Inhibits phagocytosis		
	Numerous exotoxins and extracellular enzymes	Multiple blood vessels red blood cells leukocytes myocardium etc	Cytotoxic hemolytic various hydrolytic enzyme reactions		
Bacillus anthracis	D polyglutamic acid capsule	Phagocytes	*Inhibits phagocytosis*		Antibodies to capsular material not protective See *text*
	Extracellular toxin	Generalized	Damages phagocytes produces edema and necrosis shock oligemia and death	Antibodies to toxin or possibly to spontaneously toxoided derivatives	

TABLE 1 FACTORS THAT INFLUENCE PATHOGENICITY OF SOME BACTERIAL SPECIES (*Continued*)

BACTERIAL SPECIES	NATURE	SITE OF ACTION	MODE OF ACTION	SPECIFIC IMMUNITY TO INFECTION	COMMENT
Pasteurella pestis	Envelope or capsular antigen (Fraction I) carbohydrate protein complex	Phagocytes	Inhibits phagocytosis		Fraction I evokes protective antibodies in rats mice rabbits and monkeys when given in saline or oil protective to guinea pigs if given in oil in doses not exceeding 500 μg antibodies to VW protect mice against infection by virulent strains that lack envelope antigen role of Fraction I in mouse virulence is not clear
	VW antigen complex	Pha ocytes	Inhibits phagocytosis of *P pestis* by mouse cells	Antibodies to envelope antigen (Fraction I) antibodies to VW complex in mice	
	Extracellular protein toxin	Phagocytes liver (?) kidney (?)	Prevents destruction of *P pestis* by damaging phagocytes		
Corynebacterium diphtheriae	Exotoxic protein	Cells of most tissues	Necrotizing inhibits protein synthesis inhibits oxidative processes possibly through interference with cytochrome b	Antitoxin	Toxin produced following infection with appropriate diphtherial bacteriophages
Clostridium botulinum	Exotoxic protein	Cholinergic nerve endings in peripheral autonomic and somatic fibers	Anticholinergic inhibits release of acetylcholine	Antitoxin	Six types of *Cl botulinum* A B C D E F produce immunologically distinct toxins
Clostridium welchii	Lecithinase exotoxin	Lecithin of cell membranes and mitochondria	Cytolytic	Antilecithinase	

	Collagenase	Collagen framework of intact tissues	Proteolytic		Destroys collagen framework in intact muscle Antibodies to collagenase and *hyaluronidase not* protective against infection
	Hyaluronidase	Intercellular ground substance	Depolymerizes hyaluronic acid		
Clostridium tetani	Exotoxic protein	Motor neurons in cerebrospinal axis	Anticholinergic (?) abolishes *synaptic* inhibition	Antitoxin	Toxin is bound by ganglioside of nervous tissue
Salmonella typhosa	O antigens polysaccharide protein phospholipid complex	Circulating phagocytes and RES cells serum factors small blood vessels	Inhibits phagocytosis inhibits complement modifies fibrinogen potentiates effects of epinephrine etc	Antibodies to cells containing *O antigen*	
	Vi antigen (polysaccharide)	Phagocytes	Antiphagocytic		

TABLE I FACTORS THAT INFLUENCE PATHOGENICITY OF SOME BACTERIAL SPECIES (*Continued*)

BACTERIAL SPECIES	NATURE	SITE OF ACTION	MODE OF ACTION	SPECIFIC IMMUNITY TO INFECTION	COMMENT
Pasteurella pestis	Envelope or capsular antigen (Fraction I) carbohydrate protein complex	Phagocytes	Inhibits phagocytosis		Fraction I evokes protective antibodies in rats mice rabbits and monkeys when given in saline or oil protective to guinea pigs if given in oil in doses not exceeding 500 μg antibodies to VW protect mice against infection by virulent strains that lack envelope antigen role of Fraction I in mouse virulence is not clear
	VW antigen complex	Phagocytes	Inhibits phagocytosis of *P pestis* by mouse cells	Antibodies to envelope antigen (Fraction I) antibodies to VW complex in mice	
	Extracellular protein toxin	Phagocytes liver (?) kidney (?)	Prevents destruction of *P pestis* by damaging phagocytes		
Corynebacterium diphtheriae	Exotoxic protein	Cells of most tissues	Necrotizing inhibits protein synthesis inhibits oxidative processes possibly through interference with cytochrome b	Antitoxin	Toxin produced following infection with appropriate diphtherial bacteriophages
Clostridium botulinum	Exotoxic protein	Cholinergic nerve endings in peripheral autonomic and somatic fibers	Anticholinergic inhibits release of acetylcholine	Antitoxin	Six types of *Cl botulinum* A B C D E F produce immunologically distinct toxins
Clostridium welchii	Lecithinase exotoxin	Lecithin of cell membranes and mitochondria	Cytolytic	Antilecithinase

	Hyaluronidase	Intercellular ground substance	Depolymerizes hyaluronic acid		
Clostridium tetani	Exotoxic protein	Motor neurons in cerebrospinal axis	Anticholinergic (?) abolishes synaptic inhibition	Antitoxin	Toxin is bound by ganglioside of nervous tissue
Salmonella typhosa	O antigens polysaccharide protein phospholipid complex	Circulating phagocytes and RES cells serum factors small blood vessels	Inhibits phagocytosis inhibits complement modifies fibrinogen potentiates effects of epinephrine etc	Antibodies to cells containing O antigen	
	Vi antigen (polysaccharide)	Phagocytes	Antiphagocytic		

genic factor in pneumococcus the capsular polysaccharide differs entirely from tetanus toxin both in its nature and mode of action and the mechanisms by which these two bacterial species cause disease are quite different Tetanus is a highly fatal disease caused by a toxic metabolic product of a microorganism *that is incapable of multiplying in healthy* tissue whereas in pneumococcal infections the invasive bacteria cause death only after extensive multiplication in tissues of the host

Many diseases caused by bacteria fall into either one of the two categories illustrated by the foregoing examples However a larger number belong to a third category in which the microorganisms exhibit multiple pathogenic qualities as shown in Table 1

Possession of an antiphagocytic component such as a capsule does not mean that this material is the most significant factor in virulence This is well illustrated by the anthrax bacillus in which all naturally occurring virulent strains are found to be encapsulated on the other hand encapsulated strains may be avirulent It is apparent that other factors have overriding importance as compared with the capsule

To determine precisely the part that a *particular cell component plays in the pathogenicity* of a bacterial species may be very difficult In pneumococcus the situation is deceptively simple since invasiveness can be shown by a variety of methods to depend on a single morphologic structure the polysaccharide capsule which is antigenic Moreover *complete protection against infection* is provided by antipolysaccharide antibodies In general demonstration that antibodies to a cell fraction are protective has afforded the most secure basis for inferring that it determines or influences pathogenicity In cases such as the anthrax bacillus in which antibodies to the polyglutamic acid capsule do not prevent *infection more indirect methods* must be used such as the demonstration in vitro that the capsule inhibits phagocytosis In Group A and Group C streptococci the hyaluronic acid capsules are not antigenic but appear to influence pathogenicity because it has been shown that infected animals may be afforded a degree of protection if they are injected with the enzyme hyaluronidase which digests away the hyaluronic acid capsule in vivo

If antibodies to a cell product prevent infection this is very strong evidence that it is a virulence factor For example, antibodies to the M proteins on the surface of Group A streptococci are protective However it is *much more difficult to specify the role of* other cell products such as toxins or extracellular enzymes of streptococci in the infectious process because antibodies to them do not prevent disease although they may modify its course Demonstration that an isolated product is toxic such as the O hemolysin of several bacterial species cannot be taken to mean that it has significance as a determinant of pathogenicity At the same time one should not infer that such products have no influence on the course of disease on the grounds that antibodies to them do not prevent *initiation* of infection It would seem to be more reasonable to consider the M proteins as the primary determinants of virulence and the other cell products as secondary candidates that may come into operation after infection has been established

Pathogenic staphylococci produce during growth both in cultures and in the course of *naturally occurring infections a relatively* potent toxic protein termed alpha toxin Nonpathogenic strains do not produce it As little as 1 mcg of this substance is capable of killing a mouse (Bernheimer and Schwartz 1963) and about the same quantity injected into the skin of a rabbit results in the local *development of an impressive necrotic* lesion Striking damage in vitro to erythrocytes leukocytes platelets and tissue-culture cells can be demonstrated Despite these properties the extent to which alpha toxin contributes to the pathogenesis of staphylococcal disease is not clearly understood for some humans who have substantial amounts *of circulating antitoxin are nevertheless* susceptible to staphylococcal disease and the degree of protection afforded by specific antitoxin to artificially infected animals seems to depend on the experimental conditions selected by the investigator

The species listed in Table 1 have been chosen to exemplify the multiplicity of factors that are involved in the *pathogenicity of*

bacteria and to indicate something of their nature and mode of action Complete information is not available for any species Even in the case of pneumococcus which has been studied more extensively than any of the other species shown in Table 1 we are entirely ignorant of the factor or factors produced by it which cause death of the infected host It is abundantly clear that the nontoxic polysaccharide capsules are of primary importance in enabling pneumococcus to be invasive and equally plain that death of the host cannot be ascribed to a direct toxic action of the polysaccharides

1 *Nontoxic antigenic surface components which act by inhibiting phagocytosis and antibodies to which are protective* The polysaccharide capsules of pneumococci already referred to are examples of this category Through inhibition of phagocytosis they permit multiplication of bacteria in the tissues Antibodies to them promote phagocytosis and protect against infection Many other important pathogens such as *Hemophilus influenzae* and *Klebsiella pneumoniae* likewise owe their chief pathogenic activity to the protection against phagocytosis afforded by antigenic polysaccharide capsules

A surface antigen of *Staphylococcus aureus* consisting principally of polysaccharide has been isolated by Morse (1962) This substance appears to be responsible for resistance to engulfment by phagocytes because absorption of antiserum with it removes opsonizing antibody moreover injection of the antigen into mice results in protection against intraperitoneal challenge with the homologous strain However the antigen appears to be absent from a number of other strains of *Staph aureus* and the general significance of the observations has still to be evaluated

Proteins on the bacterial surface may act in a similar way Group A streptococci (*Streptococcus pyogenes*) can be differentiated into many types based on immunologically distinct acid soluble M proteins which are present at the cell surface Although Group A streptococci produce many other components toxins and enzymes which may play a pathogenic role once infection has been established the ability to initiate the disease process depends in the main on the antiphagocytic activity of the M proteins Moreover anti M antibodies are protective whereas antibodies to other cell products although they may modify the disease do not prevent infection

Naturally occurring fully virulent *Pasteurella pestis* produces a surface material referred to as envelope antigen capsular antigen or Fraction 1 which inhibits phagocytosis It appears to be a carbohydrate protein complex Antibodies to it protect against experimental infection in mouse rat guinea pig monkey and presumably in man (for review see Burrows 1955) Burrows (1957) has described a second antiphagocytic material termed the VW antigen complex which is also toxic for leukocytes Mouse virulent mutants of the plague bacillus occur that lack capsular antigen In these strains the toxic antiphagocytic VW complex appears to be responsible for virulence Antibodies to the capsular antigen (Fraction 1) alone do not protect mice against infection with noncapsulated strains that contain VW However virulent strains as encountered in nature possess both capsular and VW antigens and at least in experimental infections of mouse rat and monkey antibodies to both antiphagocytic materials do not appear to be necessary for protection but only the anticapsular antibodies A maximum degree of protection may require both antibodies Discovery of the VW antigens provides an explanation for the older observations that although fully virulent wild type *P pestis* are encapsulated not all encapsulated strains are virulent It may be that the latter lack the VW antigens

2 *Nontoxic antigenic surface components which inhibit phagocytosis but antibodies to which are not protective* All pathogenic strains of *Bacillus anthracis* form capsules composed chiefly of D polyglutamic acid which has antiphagocytic properties However capsulated but nonvirulent strains exist as mentioned earlier The capsular material is antigenic but antibodies to it fail to protect animals against infection A protective antigen distinct from the polyglutamic acid capsule is produced during the course of infection and is present in edema fluid which can be used to immunize animals against the disease Under appropriate cultural con

ditions as shown by Gladstone (1946), the *protective antigen is formed in artificial culture medium* and this finding is the basis for the preparation of the immunizing materials currently in use for the protection of man (Wright *et al* 1954 Strange and Belton 1954) An exotoxin described by Smith and Keppie and their colleagues (see Smith and Keppie 1955) is lethal for laboratory animals and produces edema following injection into the skin It consists of 3 components called Factors I II and III each of which is a protein and each of which by itself is nontoxic A combination of I and II is both edema producing and lethal while addition of III to the combination results in a decrease in its capacity to provoke edema but in an increase in lethality (See Stanley and Smith 1961 1963 and Beall Taylor and Thorne 1962) Of the 3 factors II is the only one which when injected by itself into guinea pigs immunizes them against infection with *B anthracis* while addition of the other two alters the capacity of II to do so Preparations currently used for immunization of man against anthrax contain II and III The antiphagocytic polyglutamic acid capsule although uniformly possessed by virulent strains, is not a part of the protective antigen

3 *Nontoxic nonantigenic surface components which inhibit phagocytosis* Two examples may be cited the hyaluronic acid capsules of streptococci of Groups A and C and the fibrin coating derived from the host which is deposited on the surface of staphylococci that form coagulase

In addition to M proteins at the cell surface which on the basis of immunologic evidence are the primary determinants of pathogenicity, Group A streptococci form a second surface component hyaluronic acid that is also antiphagocytic though less active than the M proteins Hyaluronic acid is nonantigenic in man and other animals because similar or identical polymerized acidic polysaccharides are distributed throughout the animal body as constituents of the intercellular ground substance Evidence for the pathogenic role of hyaluronic acid in streptococci was obtained originally by Hirst (1941) who found that experimental infections of mice by Group C streptococci can be modified by injecting crude hyaluronidase preparations from leeches which act by depolymerizing the polysaccharide Hirst found no effect of hyaluronidase in Group A infections Subsequently Kass and Seastone (1944) using hyaluronidase prepared from bull testes reported a modifying effect on Group A infections of mice

For many years *coagulase* a product of most strains of pathogenic staphylococci was considered to be a virulence factor Coagulase is an enzyme or enzyme activator which in concert with a factor present in plasma of certain species, converts fibrinogen to fibrin It was held that coagulase acts by causing a fibrin coat to be deposited on the bacteria which protects them from phagocytosis (Smith Hale and Smith 1947) However, a primary role for coagulase in the pathogenicity of *Staphylococcus pyogenes* has not been proved At the present time it is more reasonable to consider coagulase production as one of the properties which characterize the species *Staphy pyogenes* along with many others such as production of golden pigment and α hemolysin ability to ferment mannitol and susceptibility to lysis by a variety of bacteriophages

4 *Toxic antigenic surface components (O antigens) of the enterobacteria and other gram negative bacteria* These substances termed endotoxins, are lipopolysaccharides whose role in infections and other pathologic conditions has been studied extensively Endotoxins are discussed in detail in a chapter which follows

5 *Exotoxic proteins which account for the principal pathogenic properties of bacteria* This category is exemplified by the classic exotoxins produced by *C diphtheriae Cl tetani* and *Cl botulinum* Injection into animals of the purified toxins in minute amounts reproduces the significant pathologic changes in each case and antibodies directed against the toxins are protective In none of these diseases is there invasion of the living tissues of the host indeed *Cl botulinum* should not be classed as an infectious agent The toxins of the 6 types of *Cl botulinum* are formed outside the animal body and, following ingestion are absorbed through the wall of the gut.

A brief description of the chemistry and the pharmacology of some important bacterial exotoxins is given in a subsequent section

6 *Extracellular products of bacteria that are not the principal pathogenic factors but may contribute to the disease picture* Examples which fall into this category are numerous In some instances the evidence is good for their participation in the natural disease in many there is as yet no solid evidence that they contribute to the pathologic changes In a third group such as the hyaluronidases of many bacterial species and the collagenase of *Cl welchii* although the experimental evidence would appear to rule them out as significant pathogenic factors doubt lingers as to whether or not it is adequate to exclude them entirely

Many of the substances in this category are extracellular enzymes that are produced during or shortly after active growth of the bacteria in vitro The manner in which they are released from the bacteria is not understood but may involve autolysis in some instances Some of them—for example the proteolytic enzyme of *Str pyogenes* and the ε toxin of *Cl welchii*—are released as inactive precursors that subsequently undergo conversion to active enzyme or toxin respectively The extracellular products are excreted during growth of the microorganisms also in natural disease as may be determined either by their pathologic effects or because specific antibodies to them appear during disease or in convalescence

Group A streptococci produce a greater number of extracellular toxic and enzymatic products than are recognized for most other human pathogens As many as 20 extracellular streptococcal antigens are detectable using normal pooled human gamma globulin as a source of antibodies (Halbert and Auerbach 1961) and only a minority of the antigens are identifiable with products of defined toxic or enzymatic activity Of these *erythrogenic* or *scarlatinal toxin* is responsible for the skin rash in scarlet fever which is essentially a streptococcal infection caused by a toxin producing strain in a person who has not acquired immunity to the toxin But erythrogenic toxin has no influence on the ability of streptococci to initiate infection so far as we are aware Its effect becomes apparent after invasion by streptococci has occurred Antibodies to the toxin which specifically neutralize its toxic action appear on recovery The manner in which erythrogenic toxin affects the small blood vessels to produce the scarlatinal blush is unknown

Most strains of hemolytic streptococci of Group A as well as some Group C and G strains produce an extracellular enzyme *streptokinase* which brings about digestion of fibrinogen and lysis of fibrin clots The remarkable specificity of streptokinase for fibrin was first described by Tillett and Garner (1933) who termed it fibrinolysin Subsequently it was shown by Christensen and MacLeod (1945) that it is a kinase which activates an enzyme precursor plasminogen in the plasma of man and animals to form the proteolytic enzyme plasmin Plasmin has affinity for fibrin and fibrinogen both in the test tube and in vivo and it seems likely that the thin exudates characteristic of streptococcal infections are due to the action of streptokinase At any rate as soon as the antibody antistreptokinase makes its appearance during the disease in man the exudates become thick and fibrinous presumably because antibody has neutralized the kinase It is not known whether streptokinase has other pathologic effects although both it and streptococcal hyaluronidase have been invoked to explain the typically rapid extension of streptococcal cellulitis through digestion of fibrin barriers and the intercellular ground substance Antistreptokinase does not prevent infection and information is not available that demonstrates whether it modifies the disease except as indicated above

In addition to erythrogenic toxin and streptokinase Group A streptococci produce two extracellular hemolysins or cytolysins streptolysin O and streptolysin S neither of which has been shown to take part in the pathogenesis of the infection although both are very powerful cytotoxins that cause death of animals when injected with very small doses Streptolysin O is released during infection as indicated by antibody production to it Streptolysin S in all probability is also excreted by the bacteria during disease but is not so easily detectable because either it

is not antigenic or else the antibody to it does not neutralize its toxic action

Streptolysin O is a protein which is readily oxidized to an inactive form by atmospheric oxygen It is related antigenically to oxygen labile hemolysins produced by pneumococcus (pneumolysin) *Cl tetani* (tetanolysin) and *Cl welchii* (θ toxin) Significantly none of the O hemolysins of these 3 species in common with streptolysin O has been shown to affect the course of natural or experimental disease

Certain strains of Group A streptococci produce an extracellular proteolytic enzyme of the papain type which is activated by KCN and sulfhydryl compounds The enzyme destroys M protein present on the surface of living cells and streptococci which produce large amounts are avirulent for mice Enhancement of virulence by mouse passage is accompanied by a diminished capacity of strains to produce the proteinase (Elliott 1945) Although production of the enzyme may affect the virulence of the bacterial cells themselves through digestion of M protein there is no evidence that its production in vivo is detrimental to the tissues of the infected host

Wilson (1957) has investigated the leukotoxicity of streptococci a property first described in 1918 by Levaditi This effect which is entirely distinct from the leukocidal action of the oxygen labile hemolysin streptolysin O occurs only after the bacteria are ingested and results in death of the phagocyte Filtrates of leukotoxic streptococci do not damage the phagocytes and a protective effect of antiserum cannot be demonstrated It appears that the leukotoxin is able to damage cells only if it is liberated within them and to this end the streptococci serve as Trojan horses Leukotoxin is produced by many but not all strains of Group A streptococci and its formation is associated especially with certain M types such as Type 12 The formation of leukotoxin is not correlated with mouse virulence Bernheimer Lazarides and Wilson (1957) have documented an interesting association between leukotoxicity and the production by certain strains of an enzyme streptococcal DPNase which destroys the coenzyme diphosphopyridine nucleotide The identity of leukotoxin and DPNase has not been proved As in the case of a number of other streptococcal extracellular products no correlation has been shown between their activity and virulence but as Wilson (1957) points out it is possible that in the contest between the invading bacteria and the cells of the host the leukotoxin might at times determine whether infection will be established or not The same might be said of other activities of Group A streptococci

Although apparently bearing no relationship to the phenomenon just described streptolysins O and S are known to destroy leukocytes in vitro (Todd 1942 Bernheimer and Schwartz 1960) Recently both of these agents have been shown to bring about the release of hydrolytic enzymes from lysosomes isolated from various tissues (Weissmann Keiser and Bernheimer 1963) In view of the lysosomal nature of the leukocytic granules it has been suggested that streptolysins O and S might disrupt the granules in intact white cells thereby releasing autolytic enzymes which in turn would digest other leukocyte structures resulting eventually in cell death Consistent with this concept is the finding that early rapid and extensive lysis of cytoplasmic granules does indeed occur when leukocytes are exposed to streptolysins (Hirsch Bernheimer and Weissmann 1963)

Cl welchii the most frequent cause of gas gangrene in common with other clostridia produces a powerful proteolytic enzyme *collagenase* which is capable of disintegrating muscle of laboratory animals in vivo by decomposing the reticular framework Pulping of affected muscles is a characteristic of clostridial myositis However it is by no means clear that collagenase contributes in a significant way to the pathogenesis of infection by *Cl welchii* Indeed the weight of evidence is against it since the specific antibody anticollagenase neither prevents infection nor appears to modify its course Similarly antibodies to *Cl welchii hyaluronidase* do not prevent infection nor do they mitigate the progress of the lesion Protection against infection depends on antibodies to the *α toxin* a *lecithinase* which hydrolyzes lecithin to phosphoryl choline and a diglyceride The lecithinase causes rapid lysis of erythrocytes

and necrosis of other cells and can account for most of the severe local effects following infection by *Cl welchii* However it is not proved that death from gas gangrene is caused by *α toxin absorbed from the involved* muscle and disseminated throughout the body Profound shock is seen in severe and fatal cases but free toxin is not demonstrable in the circulation nor does intravascular hemolysis occur except in cases of septic abortion in which in contrast with clostridial myositis the clostridia themselves are present in the blood

VARIATIONS IN VIRULENCE ASSOCIATED WITH THE PRODUCTION OF DIFFERENT AMOUNTS OF A PATHOGENIC FACTOR

Variations in virulence between strains of the same species or type may depend not only on the presence or the absence of a factor known to be concerned in pathogenicity but also on the amount produced For example in pneumococcus loss of capsulation through S ⟶ R mutation results in loss of virulence Mutants of intermediate virulence are commonly encountered and in strains of 3 different types it has been shown that virulence for mice is correlated with the amount of capsular polysaccharide produced *in vitro (MacLeod and Krauss 1950)* Studies by Wood (for summary see Wood 1951 52) explain in part the influence of different amounts of polysaccharide on virulence, since he has shown the pneumococci that possess large capsules are phagocyted with great difficulty Moreover if a strain produces large amounts of polysaccharide a lag in opsonization results because the host must produce larger amounts of specific antibody to combine with the excess of free polysaccharide in the tissues and body fluids as well as that present on the surface of the bacteria themselves The delay in opsonization permits more extensive multiplication Differences in capsule size corresponding to the amount of polysaccharide formed in vitro can be demonstrated in vivo In *Klebsiella pneumoniae* it has been found also that the amount of capsular polysaccharide and its rate of production bear a relationship to virulence (Ehrenworth and Baer, 1956)

A similar quantitative relationship may exist in diphtheria bacilli in which the exotoxin is the chief determinant of pathogenicity The simplest explanation of why *gravis* strains in general cause a more severe type of diphtheria than *mitis* strains would be that they are able to produce more toxin in vivo Pappenheimer and Johnston (1936) showed that the amount of iron present in the medium in which toxigenic diphtheria bacilli are growing determines the amount of toxin formed Under the conditions of their studies the amount of toxin increased as the iron concentration was increased up to 100 mcg of iron per liter which yielded peak toxin production As iron was increased beyond 100 micrograms per liter toxin production declined although growth improved At 500 mcg Fe per liter toxin production no longer could be demonstrated In explanation of the seemingly paradoxical relation between iron and toxin production it should be pointed out that whereas iron is essential for growth of the organisms no toxin is formed by the bacteria until the medium has been exhausted of iron (Mitsuhashi Kurokawa and Kojima 1949) At iron concentrations found optimal for toxin formation by laboratory strains no correlation has been found between toxin production of different strains isolated from patients and the severity of the disease they cause *Mueller (1941) observed that the* amount of iron present in diphtheritic membrane is many times that found to be optimal for toxin formation in vitro and that if a correlation exists between the amount of toxin and clinical severity it should be looked for under conditions where iron is in excess Mueller tested a *gravis* strain and 3 *mitis* strains under these conditions and found that in the presence of excess iron the *gravis* strain formed from 12 to 15 times as much toxin as the *mitis* strains Therefore it is tempting to relate differences in virulence of diphtheria bacilli to toxin production at high iron concentrations although this has not been shown to occur in vivo Pappenheimer (1955) has reported the growth rate of a *gravis* strain to be about 3 times as fast as a *mitis strain* the generation times being 60 and 160 minutes respectively If this difference in growth rate exists also in the diphtheritic membrane it might be expected that

is not antigenic or else the antibody to it does not neutralize its toxic action

Streptolysin O is a protein which is readily oxidized to an inactive form by atmospheric oxygen It is related antigenically to oxygen labile hemolysins produced by pneumococcus (pneumolysin) *Cl tetani* (tetanolysin) and *Cl welchii* (θ toxin) Significantly none of the O hemolysins of these 3 species in common with streptolysin O has been shown to affect the course of natural or experimental disease

Certain strains of Group A streptococci produce an extracellular proteolytic enzyme of the papain type which is activated by KCN and sulfhydryl compounds The enzyme destroys M protein present on the surface of living cells and streptococci which produce large amounts are avirulent for mice Enhancement of virulence by mouse passage is accompanied by a diminished capacity of strains to produce the proteinase (Elliott 1945) Although production of the enzyme may affect the virulence of the bacterial cells themselves through digestion of M protein there is no evidence that its production in vivo is detrimental to the tissues of the infected host

Wilson (1957) has investigated the leukotoxicity of streptococci a property first described in 1918 by Levaditi This effect which is entirely distinct from the leukocidal action of the oxygen labile hemolysin streptolysin O occurs only after the bacteria are ingested and results in death of the phagocyte Filtrates of leukotoxic streptococci do not damage the phagocytes and a protective effect of antiserum cannot be demonstrated It appears that the leukotoxin is able to damage cells only if it is liberated within them and to this end the streptococci serve as Trojan horses Leukotoxin is produced by many but not all strains of Group A streptococci, and its formation is associated especially with certain M types such as Type 12 The formation of leukotoxin is not correlated with mouse virulence Bernheimer Lazarides and Wilson (1957) have documented an interesting association between leukotoxicity and the production by certain strains of an enzyme streptococcal DPNase which destroys the coenzyme diphosphopyridine nucleotide The identity of leukotoxin and DPNase has not been proved As in the case of a number of other streptococcal extracellular products no correlation has been shown between their activity and virulence but as Wilson (1957) points out it is possible that in the contest between the invading bacteria and the cells of the host the leukotoxin might at times determine whether infection will be established or not The same might be said of other activities of Group A streptococci

Although apparently bearing no relationship to the phenomenon just described streptolysins O and S are known to destroy leukocytes in vitro (Todd 1942 Bernheimer and Schwartz 1960) Recently both of these agents have been shown to bring about the release of hydrolytic enzymes from lysosomes isolated from various tissues (Weissmann Keiser and Bernheimer 1963) In view of the lysosomal nature of the leukocytic granules it has been suggested that streptolysins O and S might disrupt the granules in intact white cells thereby releasing autolytic enzymes which in turn would digest other leukocyte structures resulting eventually in cell death Consistent with this concept is the finding that early rapid and extensive lysis of cytoplasmic granules does indeed occur when leukocytes are exposed to streptolysins (Hirsch Bernheimer and Weissmann 1963)

Cl welchii the most frequent cause of gas gangrene in common with other clostridia produces a powerful proteolytic enzyme *collagenase* which is capable of disintegrating muscle of laboratory animals *in vivo* by decomposing the reticular framework Pulping of affected muscles is a characteristic of clostridial myositis However it is by no means clear that collagenase contributes in a significant way to the pathogenesis of infection by *Cl welchii* Indeed the weight of evidence is against it since the specific antibody anticollagenase neither prevents infection nor appears to modify its course Similarly antibodies to *Cl welchii hyaluronidase* do not prevent infection nor do they mitigate the progress of the lesion Protection against infection depends on antibodies to the *α toxin* a *lecithinase* which hydrolyzes lecithin to phosphoryl choline and a diglyceride The lecithinase causes rapid lysis of erythrocytes

and necrosis of other cells and can account for most of the severe local effects following infection by *Cl welchu* However it is not proved that death from gas gangrene is caused by *α toxin absorbed from the involved muscle* and disseminated throughout the body Profound shock is seen in severe and fatal cases but free toxin is not demonstrable in the circulation nor does intravascular hemolysis occur except in cases of septic abortion in which in contrast with clostridial myositis the clostridia themselves are present in the blood

VARIATIONS IN VIRULENCE ASSOCIATED WITH THE PRODUCTION *OF DIFFERENT AMOUNTS OF A* PATHOGENIC FACTOR

Variations in virulence between strains of the same species or type may depend not only on the presence or the absence of a factor known to be concerned in pathogenicity but also on the amount produced For example in pneumococcus loss of capsulation through S ⟶ R mutation results in loss of virulence Mutants of intermediate virulence are commonly encountered and in strains of 3 different types it has been shown that virulence for mice is correlated with the amount of capsular polysaccharide produced in vitro (MacLeod and Krauss 1950) Studies by Wood (for summary see Wood 1951 52) explain in part the influence of different amounts of polysaccharide on virulence since he has shown the pneumococci that possess large capsules are phagocyted with great difficulty Moreover if a strain produces large amounts of polysaccharide a lag in opsonization results because the host must produce larger amounts of specific antibody to combine with the excess of free polysaccharide in the tissues and body fluids as well as that present on the surface of the bacteria themselves The delay in opsonization permits more extensive multiplication Differences in capsule size corresponding to the amount of polysaccharide formed in vitro can be demonstrated in vivo In *Klebsiella pneumoniae* it has been found also that the amount of capsular polysaccharide and its *rate of production bear a relationship to virulence* (Ehrenworth and Baer 1956)

A similar quantitative relationship may exist in diphtheria bacilli in which the exotoxin is the chief determinant of pathogenicity The simplest explanation of why *gravis* strains in *general cause a more severe type of diph*theria than *mitis* strains would be that they are able to produce more toxin in vivo Pappenheimer and Johnston (1936) showed that the amount of iron present in the medium in which toxigenic diphtheria bacilli are growing determines the amount of toxin formed Under the conditions of their studies the amount of toxin increased as the iron concentration was increased up to 100 mcg of iron per liter which yielded peak toxin production As iron was increased beyond 100 micrograms per liter toxin production declined although growth improved At 500 mcg Fe per liter toxin production no longer could be demonstrated In explanation of the seemingly paradoxical relation between iron and toxin production it should be pointed out that whereas iron is essential for growth of the organisms no toxin is formed by the *bacteria until the medium has been exhausted* of iron (Mitsuhashi Kurokawa and Kojima 1949) At iron concentrations found optimal for toxin formation by laboratory strains no correlation has been found between toxin production of different strains isolated from patients and the severity of the disease they cause Mueller (1941) observed that the amount of iron present in diphtheritic membrane is many times that found to be optimal for toxin formation in vitro and that if a correlation exists between the amount of toxin and clinical severity it should be looked for under conditions where iron is in excess Mueller tested a *gravis* strain and 3 *mitis* strains under these conditions and found that in the presence of excess iron the *gravis* strain formed from 12 to 15 times as much toxin as the *mitis* strains Therefore it is tempting to relate differences in virulence of diphtheria bacilli to toxin production at high iron concentrations although this has not been shown to occur in vivo Pappenheimer (1955) has reported the growth rate of a *gravis* strain to be about 3 times as fast as a *mitis strain* the generation times being 60 and 160 minutes respectively If this difference *in growth rate exists also in the diph*theritic membrane it might be expected that

gravis strains would produce more toxin in vivo The precise relationship of iron concentration to the bacteriophage infection of *C diphtheriae* which must be present if toxin is to be formed (Freeman 1951) has not been defined (for discussion see Pappenheimer 1955)

ENHANCEMENT OF VIRULENCE

Enhancement of bacterial virulence is readily demonstrable experimentally on animal passage of bacterial strains For example most Group A streptococcal strains and some pneumococci on primary isolation from man are of low virulence for mice By repeated mouse passage virulence of pneumococcus may be increased from an LD_{50} of 100 000 bacteria or more to a degree where less than 10 cocci uniformly cause fatal infection Enhancement of virulence by animal passage results from selection of virulent mutants present in the original heterogeneous culture or that have arisen on multiplication in the animal body

It is commonly believed that during the course of epidemic disease in man the virulence of the infecting agent increases While this seems to be reasonable and may be true there is no objective evidence to support it The many factors involved in the spread of an epidemic disease make it almost impossible to establish that virulence has increased Perhaps the greatest difficulty in analysis lies in the fact that virulence for laboratory animals is rarely a measure of virulence for man and since virulence for man cannot be determined under accurately controlled conditions any inferences must be based on epidemiologic analysis Such analysis has not brought forth proof of increasing bacterial or viral virulence during the course of a human epidemic To the contrary it would appear more likely that a highly virulent and communicable mutant was selected through one means or another *before* the epidemic began If this were not the case it is difficult to visualize how an epidemic could start

A possible exception to the remarks in the preceding paragraph is the appearance of drug resistant mutants of bacteria under circumstances where large numbers of infected persons are treated over an extended period or where the drugs are used in low dosage for prophylaxis Under such circumstances sulfonamide resistant gonococci and Group A streptococci have appeared and have partially replaced the sufonamide susceptible strains previously encountered as the causes of epidemic disease of man There is no evidence that the resistant mutants are more virulent for *normal* man than susceptible strains However the additional attribute of drug fastness which enables resistant strains to cause disease in persons treated with sulfonamides, can perhaps be termed an enhancement of virulence since sulfonamide sensitive strains are not able to cause disease under the same circumstances

Virulence is also said to be increased by certain artificial methods such as the injection of bacteria suspended in mucin Enhancement of virulence by such methods should be regarded as more apparent than real Meningococci typhoid bacilli staphylococci and some other bacterial species are quite avirulent for mice and to cause death these animals must be injected in relatively enormous doses often 0 1 to 1 ml of broth culture The number of living organisms required to bring about a fatal infection does not differ markedly from the number of heat killed bacteria or their toxic products which cause death on injection If living meningococci or typhoid bacilli are suspended in a viscous protective medium such as mucin fatal infections result in mice after intraperitoneal injection of only a few bacteria The small inoculum protected by a surrounding coating of mucin presumably multiplies until sufficient bacteria are present to constitute a lethal toxic dose It may be added that studies of virulence in laboratory animals using bacteria suspended in mucin have provided little insight into the mechanisms involved in virulence and moreover have no relationship to virulence for man

Just as the virulence of bacteria may be increased by selection through repeated animal passage so it may often decrease by continued cultivation on artificial media The process again appears to be one of selection in this case of *less* virulent mutants Many examples of such loss of virulence on laboratory media following isolation might be given of which only one will be discussed

here *Cl septicum* a strict anaerobe not infrequently associated with wound infections in man produces a potent exotoxin when cultivated in meat broth following isolation from the infected tissue If the organisms are transferred a few times in a chemically de fined medium which supports luxuriant growth their capacity to produce this toxin is lost and at the same time the strain loses its virulence (Bernheimer, 1944) If such cultures are plated on blood agar the colonies are found to be rough in form as contrasted with the smooth colonies formed by freshly isolated virulent toxin producing strains It seems probable that the chemically defined medium is lacking in some growth factor present in animal tissue which is required by the smooth virulent organisms but is not required by the rough mutants The factor is apparently present in meat broth since the change from smooth to rough occurs more slowly on transfer in this medium

CHEMISTRY AND PHARMACOLOGY OF BACTERIAL TOXINS

Classic Exotoxins of Gram Positive Bacteria

Several examples of diffusible toxins pro duced by gram positive bacteria have been referred to already These substances have been called exotoxins because they are found in filtrates of growing organisms exhibiting no visible evidence of autolysis or else are found to increase in amount parallel with growth In some instances such as *Cl botu linum* and *Cl tetani* the yield of toxin is increased on autolysis Exotoxins are charac teristic of gram positive bacteria and are produced by many pathogenic species Gram negative bacteria on the other hand produce lipopolysaccharide endotoxins which form a part of the O or somatic antigen and are intimately associated with the structural in tegrity of the cells They are not liberated into the medium unless autolysis has oc curred An exception among gram negative bacteria is the type species *Shigella dysen teriae* that produces a very potent protein exotoxin the so-called shiga neurotoxin dis tinct from the endotoxin Antibodies to the neurotoxin neutralize its toxicity but do not

TABLE 2 AMINO ACID COMPOSITION OF TETANUS AND BOTULINUS TOXINS AND OF RABBIT α GLOBULIN (ANTIBODY TO PNEUMOCOCCAL POLYSACCHARIDES)

	Tetanus Toxin[1]	Botulinus Toxin Type A	Rabbit[3] Globulin

protect against infection It is not established that shiga neurotoxin contributes to the path ogenic properties of *Sh dysenteriae* under natural conditions

The toxins produced by *C diphtheriae Cl tetani* and *Cl botulinum* type A have been isolated in highly purified form as heat labile proteins Indeed the toxins of tetanus (Pillemer *et al* 1946) and type A botulinus

gravis strains would produce more toxin in vivo The precise relationship of iron concentration to the bacteriophage infection of *C diphtheriae* which must be present if toxin is to be formed (Freeman 1951) has not been defined (for discussion see Pappenheimer 1955)

ENHANCEMENT OF VIRULENCE

Enhancement of bacterial virulence is readily demonstrable experimentally on animal passage of bacterial strains For example, most Group A streptococcal strains and some pneumococci on primary isolation from man are of low virulence for mice By repeated mouse passage virulence of pneumococcus may be increased from an LD_{50} of 100 000 bacteria or more to a degree where less than 10 cocci uniformly cause fatal infection Enhancement of virulence by animal passage results from selection of virulent mutants present in the original heterogeneous culture or that have arisen on multiplication in the animal body

It is commonly believed that during the course of epidemic disease in man the virulence of the infecting agent increases While this seems to be reasonable and may be true there is no objective evidence to support it The many factors involved in the spread of an epidemic disease make it almost impossible to establish that virulence has increased Perhaps the greatest difficulty in analysis lies in the fact that virulence for laboratory animals is rarely a measure of virulence for man and since virulence for man cannot be determined under *accurately controlled conditions* any inferences must be based on epidemiologic analysis Such analysis has not brought forth proof of increasing bacterial or viral virulence during the course of a human epidemic To the contrary it would appear more likely that a highly virulent and communicable mutant was selected through one means or another *before* the epidemic began If this were not the case it is difficult to visualize how an epidemic could start

A possible exception to the remarks in the preceding paragraph is the appearance of drug resistant mutants of bacteria under circumstances where large numbers of infected persons are treated over an extended period or where the drugs are used in low dosage for prophylaxis Under such circumstances sulfonamide resistant gonococci and Group A streptococci have appeared and have partially replaced the sufonamide susceptible strains previously encountered as the causes of epidemic disease of man There is no evidence that the resistant mutants are more virulent for *normal* man than susceptible strains However the additional attribute of drug fastness which enables resistant strains to cause disease in persons treated with sulfonamides can perhaps be termed an enhancement of virulence since sulfonamide sensitive strains are not able to cause disease under the same circumstances

Virulence is also said to be increased by certain artificial methods such as the injection of bacteria suspended in mucin Enhancement of virulence by such methods should be regarded as more apparent than real Meningococci typhoid bacilli staphylococci and some other bacterial species are quite avirulent for mice and to cause death these animals must be injected in relatively enormous doses often 0 1 to 1 ml of broth culture The number of living organisms required to bring about a fatal infection does not differ markedly from the number of heat killed bacteria or their toxic products which cause death on injection If living meningococci or typhoid bacilli are suspended in a viscous protective medium such as mucin fatal infections result in mice after intraperitoneal injection of only a few bacteria The small inoculum protected by a surrounding coating of mucin presumably multiplies until *sufficient bacteria are present to constitute* a lethal toxic dose It may be added that studies of virulence in laboratory animals using bacteria suspended in mucin have provided little insight into the mechanisms involved in virulence and moreover have no relationship to virulence for man

Just as the virulence of bacteria may be increased by selection through repeated animal passage so it may often decrease by continued cultivation on artificial media The process again appears to be one of selection in this case of *less* virulent mutants Many examples of such loss of virulence on laboratory *media following isolation might* be given of which only one will be discussed

here *Cl septicum* a strict anaerobe not infrequently associated with wound infections in man produces a potent exotoxin when cultivated in meat broth following isolation from the infected tissue If the organisms are transferred a few times in a chemically de fined medium which supports luxuriant growth their capacity to produce this toxin is lost and at the same time the strain loses its virulence (Bernheimer 1944) If such cultures are plated on blood agar the colonies are found to be rough in form as contrasted with the smooth colonies formed by freshly isolated virulent toxin producing strains It seems probable that the chemically defined medium is lacking in some growth factor present in animal tissue which is required by the smooth virulent organisms but is not required by the rough mutants The factor is apparently present in meat broth since the change from smooth to rough occurs more slowly on transfer in this medium

CHEMISTRY AND PHARMACOLOGY OF BACTERIAL TOXINS

Classic Exotoxins of Gram Positive Bacteria

Several examples of diffusible toxins pro duced by gram positive bacteria have been referred to already These substances have been called exotoxins because they are found in filtrates of growing organisms exhibiting no visible evidence of autolysis or else are found to increase in amount parallel with growth In some instances such as *Cl botu linum* and *Cl tetani* the yield of toxin is increased on autolysis Exotoxins are charac teristic of gram positive bacteria and are produced by many pathogenic species Gram negative bacteria on the other hand produce lipopolysaccharide endotoxins which form a part of the O or somatic antigen and are intimately associated with the structural in tegrity of the cells They are not liberated into the medium unless autolysis has oc curred An exception among gram negative bacteria is the type species *Shigella dysen teriae* that produces a very potent protein exotoxin the so-called shiga neurotoxin dis tinct from the endotoxin Antibodies to the neurotoxin neutralize its toxicity but do not

Table 2 Amino Acid Composition of Tetanus and Botulinus Toxins and of Rabbit α Globulin (Antibody to Pneumococcal Polysaccharides)

protect against infection It is not established that shiga neurotoxin contributes to the path ogenic properties of *Sh dysenteriae* under natural conditions

The toxins produced by *C diphtheriae Cl tetani* and *Cl botulinum* type A have been isolated in highly purified form as heat labile proteins Indeed the toxins of tetanus (Pillemer *et al* 1946) and type A botulinus

have been obtained in crystalline form (Abrams *et al* 1946 Lamanna *et al* 1946) These proteins in common with shiga neurotoxin are among the most powerful poisons known It has been estimated that 1 mg of crystalline tetanus or botulinus toxin is sufficient to kill 1 000 tons of guinea pig The minimal lethal dose of botulinus toxin for the mouse is only 20 000 000 molecules Different animal species show great variation in susceptibility to bacterial toxins (Metchnikoff 1905) Man horse and guinea pig are extremely susceptible to tetanus botulinus and diphtheria toxin The mouse and the rat are only about 1/1000th as sensitive as the guinea pig to diphtheria toxin The dog while very resistant to botulinus and tetanus toxins is highly sensitive to diphtheria toxin Rabbits are approximately 10 000 times as susceptible to the killing action of shiga neurotoxin as guinea pigs

Cold blooded animals are completely resistant to large doses of tetanus botulinus and diphtheria toxins with the interesting exception of the frog and certain lizards Injection of tetanus toxin into these amphibia has no effect at low temperatures but symptoms of tetanus appear when the creatures are kept at temperatures above 20 C

On the basis of the amount of purified toxin required to produce death (LD_{50}) in a susceptible species such as the guinea pig tetanus and botulinus toxin the most poisonous substances known are about 400 times as toxic as diphtheria toxin The reason for the difference may lie in the fact that tetanus and botulinus toxins have selective affinity and toxicity for limited portions of the nervous system whereas diphtheria toxin is a general poison that is taken up by and affects any cells it comes in contact with

Chemical analysis of bacterial toxins has not provided an explanation for their extraordinary toxicity Reasonably complete information on amino acid composition of tetanus and type A botulinus toxin is available as shown in Table 2 in which for the sake of comparison data are presented for a well characterized protein rabbit γ globulin antibody to pneumococcal polysaccharides No unusual chemical groupings that can account for toxicity have been discovered Dunn *et al* (1949) have noted that in tetanus and type A botulinus toxins the ratios of aspartic acid to glutamic acid and of isoleucine to leucine are reversed as compared with most other proteins that have been studied Toxicity appears to depend on the spatial configuration of amino acids and peptide chains within the intact protein molecule and procedures which alter the protein are likely to cause loss of toxicity More recent analyses of tetanus toxin diphtheria toxin staphylococcal α toxin and the ε prototoxin of Type D *Cl welchii* indicate that these do not differ substantially in amino acid composition from the total bacterial protein

Toxoid Formation

A variety of agents which react with bacterial toxins cause irreversible loss of toxicity without loss of antigenicity or of power to combine with antitoxin All of these reagents apparently attack free amino groups they include iodine ketene (an acetylating agent) and diazonium salts However, the most commonly used reagent is dilute formaldehyde It was discovered by Glenny and Hopkins and by Ramon that crude diphtheria toxin could be completely detoxified by treatment with dilute formalin (0 4 0 5%) at slightly alkaline pH The reaction is usually complete after 3 or 4 weeks at 37 C The detoxified product termed *anatoxine* by Ramon (1928) and *toxoid* by Glenny and Hopkins (1923) retains its immunologic specificity and antigenic properties Tetanus and botulinus toxoids may be prepared in a similar manner by treatment of the corresponding toxins with formalin Diphtheria and tetanus toxoid are used on a large scale for active immunization of man against diphtheria and tetanus

The change from toxin to toxoid is a property common to most bacterial toxins and is a process which can occur spontaneously to a certain extent even at low temperatures This spontaneous detoxification without parallel loss in immunologic combining power was observed by Paul Ehrlich in 1903 who was in fact the first to use the term toxoid

Pharmacologic Action of Diphtheria Tetanus and Botulinus Toxins and Lecithinase of Cl welchii

The pharmacologic action of each of these toxins is different Diphtheria toxin causes damage to almost all types of cell in the sus

ceptible animal whereas the action of botulinus toxin is restricted to cholinergic nerve endings in peripheral autonomic and somatic fibres and tetanus toxin appears to affect only the motor neurons in the cerebrospinal axis As noted above the selectivity of action of tetanus and botulinus toxins can well account for their extraordinary toxic effect as measured by their LD_{50}, in susceptible animals The α toxin of *Cl welchii* is a lecithinase

Pappenheimer and his associates (for review see Pappenheimer 1955) have accumulated suggestive evidence that the toxity of diphtheria toxin is due to its interference with the cytochrome system of the cells of susceptible animals Toxin is formed by diphtheria bacillus only in the presence of oxygen and a supply of iron less than is necessary for optimal growth In studies of the Park Williams 8 strain which is used in most laboratories for toxin production it has been shown that bacteria harvested from cultures in which an amount of iron optimal for toxin formation is present have a very low iron content and that all iron-containing respiratory enzymes are reduced in amount This is particularly striking in the case of cytochrome b_1 the principal respiratory pigment to which 9/10ths of the hemin iron is bound As toxin is produced by iron depleted cells coproporphyrin III is also excreted into the medium The ratio of toxin to porphyrin is 1 4 the same as is present in iron-containing respiratory enzymes This observation suggested to Pappenheimer that toxin may be related to the protein portion of diphtherial cytochrome b_1 and that toxin may cause injury to the cells of susceptible animals by interfering with cytochrome b a respiratory pigment which is similar to diphtherial cytochrome b_1 and like it is concerned in succinate oxidation This ingenious scheme to account for the toxicity of diphtheria toxin has not yet been proved but strong indirect evidence for it has been presented

Macfarlane and Datta (1954) have shown that succinoxidase activity of mitochondria is reduced markedly by the α toxin (lecithinase) of *Cl welchii* The mechanism is distinct from that proposed for diphtheria toxin and is associated with hydrolysis of lecithin in the mitochondria (for discussion see review by Macfarlane 1955) Macfarlane points out that the decrease in the oxidative processes of the cells causes a shift in metabolism to glycolysis When this occurs the accumulation of organic acids would further damage the cells of the host Lecithinase of *Cl welchii* is also strongly hemolytic in vitro or on intravenous injection in animals because of digestion of lecithin of the red cell membrane However hemolysis is not a feature of the local infection clostridial myositis but does occur often to a marked degree in the bacteremia of septic abortions in which *Cl welchii* is the infecting agent The genesis of the profound shock and death seen in severe clostridial myositis is unknown Because there is no evidence of hemolysis it has been suggested that the general effects are due not to toxin carried throughout the body via the bloodstream but to some other product elaborated in the affected muscle

In contrast with the action of diphtheria toxin and lecithinase of *Cl welchii* botulinus and tetanus toxins act only on the nervous system (for review see Wright 1955) The parallelism between the sites of action of acetylcholine and botulinus toxin made it appear probable that botulinus toxin has an anticholinergic action and it has been shown that the toxin acts very widely on all parts of the peripheral nervous system that are cholinergic whether they are preganglionic or postganglionic components of the autonomic system or are the motor innervation of skeletal muscles The studies of Burgen Dickens and Zatman (1949) demonstrated that botulinus toxin depresses the release of acetylcholine and the pharmacologic effects can be explained best on this basis

Whereas botulinus toxin acts on peripheral nerves the action of tetanus toxin is in the cerebrospinal axis only and there is no clear evidence that it has any action on peripheral nerves From its site of introduction tetanus toxin travels to the central nervous system along peripheral nerves Early studies suggested travel within the axon itself but the later work of Baylis and his colleagues (1952) indicates strongly that the toxin moves centripetally in the interneuronal tissue spaces propelled by the pressure from contracting muscles and enters the interstitial tissue fluid of the central nervous system at the point of emergence of the peripheral nerve trunks from the spinal cord Its effect

have been obtained in crystalline form (Abrams *et al* 1946 Lamanna *et al* 1946) These proteins in common with shiga neurotoxin are among the most powerful poisons known It has been estimated that 1 mg of crystalline tetanus or botulinus toxin is sufficient to kill 1 000 tons of guinea pig The minimal lethal dose of botulinus toxin for the mouse is only 20 000 000 molecules Different animal species show great variation in susceptibility to bacterial toxins (Metchnikoff 1905) Man horse and guinea pig are extremely susceptible to tetanus botulinus and diphtheria toxin The mouse and the rat are only about 1/1000th as sensitive as the guinea pig to diphtheria toxin The dog while very resistant to botulinus and tetanus toxins is highly sensitive to diphtheria toxin Rabbits are approximately 10 000 times as susceptible to the killing action of shiga neurotoxin as guinea pigs

The change from toxin to toxoid is a property common to most bacterial toxins and is a process which can occur spontaneously to a certain extent even at low temperatures This spontaneous detoxification without parallel loss in immunologic combining power was observed by Paul Ehrlich in 1903 who was in fact the first to use the term toxoid

Pharmacologic Action of Diphtheria Tetanus and Botulinus Toxins and Lecithinase of Cl welchii

The pharmacologic action of each of these toxins is different Diphtheria toxin causes damage to almost all types of cell in the sus

organisms has lagged far behind knowledge of factors which influence virulence

Although communicability must be possessed by naturally pathogenic species it is not confined to virulent microorganisms The bacteria which comprise the normal flora of the skin the oropharynx the alimentary tract and the external genitalia of healthy persons are by definition communicable even though they rarely cause disease in normal persons Indeed certain of the microorganisms forming the normal flora of the alimentary canal may be essential for health through the synthesis of vitamins or the partial digestion of nutrients for which the host does not possess enzymes For example much of the vitamin K requirement of man and animals appears to be supplied by intestinal bacteria which are able to synthesize it In ruminants bacteria in the stomachs play a very important part in the digestion of food

In contrast with microorganisms that are communicable but nonvirulent are those that are virulent when introduced into the animal body but are not communicable from experimentally infected animals to normal cage mates For example pneumococci are virulent when introduced experimentally into mice by almost any route One or two cocci of the most virulent strains will cause the death of mice following intraperitoneal injection but normal mice kept in the same cage remain well

Because communicability and virulence are not necessarily interdependent it would appear that epidemic strains of a bacterial species are those in which natural selection has operated to permit the survival of variants which are concurrently highly communicable and virulent

The site of the lesions in the infected host has an important influence on communicability and this may have a bearing on the noncommunicability of pneumococcal infections in mice where the disease does not involve the respiratory tract primarily even though the bacteria are placed directly within the trachea but instead produces a rapidly fatal bacteremic infection If the disease were localized in the lungs and mice had the capacity to cough and spit pneumococcal infection might occur as an epizootic disease in this species

The influence of the site of the lesion on communicability is illustrated by plague in man which occurs in two well recognized clinical forms called bubonic and pneumonic plague The bubonic form is spread from rats to man through the bite of the rat flea Buboes form in areas adjacent to the point where the organisms are introduced through the bite of the flea and although invasion of the bloodstream commonly occurs secondary cases of plague do not arise because the bubonic form is essentially a closed infection On the other hand pneumonic plague caused by the same bacterial species *Pasteurella pestis* is contagious to those in proximity to the sufferer who expels enormous numbers of plague bacilli during coughing and in the copious discharges from the respiratory tract Secondary cases of pneumonic plague occur under certain undefined environmental circumstances because the open nature of the pulmonary lesions permits dissemination of the bacilli

A less exotic illustration of the influence of the site of the lesions on the communicability of bacteria is afforded by the hemolytic streptococcus The expression dangerous carrier has come into current usage to indicate infected individuals from whom secondary cases arise commonly Several independent investigations have shown that patients with purulent lesions discharging on the body surface as for example otitis media cervical adenitis and wound infections are more likely to transmit infection than patients with uncomplicated streptococcal pharyngitis The reason for this difference in communicability from different lesions caused by the same streptococcal strains may be because purulent lesions discharge more streptococci into the environment contaminating heavily everything in contact with the patient whereas from patients with uncomplicated pharyngitis fewer organisms are discharged into the environment therefore there is less chance of secondary cases arising

Size of the Inoculum In the case of virulence of bacteria the size of the inoculum is of great significance The same may also be true of communicability though this has not been demonstrated When a microorganism

is on motor neurons exclusively Ambache (1948) and his associates have demonstrated in local tetanus intoxication of the eye that the formation of acetylcholine is greatly reduced There is evidence therefore that both botulinus and tetanus toxin act through interference with cholinergic mechanisms and that the mode of action in each case may be similar The great difference in the action of the toxins is that tetanus acts centrally in the cerebrospinal axis whereas botulinus toxin affects only cholinergic nerve endings in peripheral somatic and autonomic fibers The degeneration of anterior horn cells observed in tetanus intoxication is believed to be a secondary manifestation and is not the cause of the characteristic symptomatology

It has been known since the 19th century that nervous tissue binds or fixes tetanus toxin in vitro In this respect brain tissue is more effective than spinal cord and gray matter more than white The constituent responsible for fixation of the toxin has been identified as ganglioside (van Heyningen 1959 van Heyningen and Miller 1961) and the capacity of ganglioside to form a complex with toxin depends in part on its content of sialic acid whose free carboxyl group is essential for fixation It is interesting and perhaps significant that ganglioside also fixes strychnine and certain other drugs which by suppressing synaptic inhibition have the same neurophysiologic action as tetanus toxin (van Heyningen 1963) Interaction of toxin with ganglioside does not appear to bring about any enzymatic alteration of this constituent of nervous tissue and hence the precise manner in which combination of toxin with ganglioside may affect motor neurons remains to be elucidated The low order of sensitivity of the frog to tetanus toxin can be attributed to the fact that frog nervous tissue has very little capacity to fix toxin (van Heyningen and Woodman 1963)

THE RELATION OF HYPERSENSITIVITY TO DISEASE PROCESSES

Although hypersensitivity to components of the bacterial cell undoubtedly plays a considerable part in the type and the progress of the lesions in many infectious diseases especially those of chronic nature little specific information is available except in the case of tuberculosis In tuberculosis in guinea pigs the effect of hypersensitivity to tuberculoproteins which in themselves are non toxic can be demonstrated readily Normal guinea pigs injected with as much as 2 ml of Koch s Old Tuberculin do not suffer any obvious ill effects On the other hand if a tuberculous guinea pig during the 8th or the 10th week of infection is injected with as little as 0 01 ml of tuberculin death may occur within a few hours An intense inflammatory reaction occurs at the site of injection and throughout the body wherever tubercles are present

The generalized tuberculin reaction in the guinea pig which ends in death illustrates the ill effects of the allergic reaction in its most severe form Less spectacular but nonetheless damaging effects due to the hypersensitive state that uniformly exists and the presence in the lesions of tubercle bacilli and their products almost certainly occur in the course of the tuberculous process in man and animals It is likely that the destructiveness of the tuberculous lesions in the adult type of tuberculosis with extensive caseation and fibrosis is strongly influenced by hypersensitivity

In other chronic bacterial infections for example brucellosis hypersensitivity to the bacteria and their products likewise may have an important influence on the character and the persistence of the lesions However this has not been clearly defined Up to the present time there is no good evidence that the hypersensitive state is part of the host s defense against infection

THE COMMUNICABILITY OF BACTERIA

A great deal more is known of the factors influencing the pathogenicity of micro-organisms than of the properties they must possess in order to be communicable from host to host under natural conditions Pathogenicity is more susceptible to experimental study because of its end result—disease—whereas organisms may be transmitted from host to host without any detectable pathologic alteration For this reason the study of properties concerned in communicability of micro

control of infectious disease by quarantine of the sick for example would be a relatively simple procedure However since perfectly well individuals either recovered from infection or who at no time have shown clinical evidence of disease may harbor the fully virulent pathogen it is apparent that for most infectious diseases quarantine of the sick is not an effective control procedure

The development of a carrier state in normal individuals who at no time have shown evidence of disease is of more significance in many instances than the persistence of the agent in recovered patients This is true in the case of meningococci for example where the number of normal persons who carry the microorganism exceeds by far those who develop meningococcal infection In this instance the person who never has been ill is of greater importance in the transmission of the microorganisms than those recovered from infection With the typhoid bacillus on the other hand the individual who has recovered from the disease is the primary source for the maintenance and the dissemination of the bacteria Therefore it is apparent that no general rule can be laid down concerning the circumstances under which pathogens can best survive in the body With different microorganisms affecting different areas of the body the conditions of parasitism vary

The ability to survive outside the animal body in which disease is produced or in which they can be carried intermittently may have considerable significance in the communicability of many bacteria The most striking illustrations of organisms having the ability to survive outside the animal body are the spore forming pathogens Anthrax spores may survive in pasture land for as long as 12 years as described by Pasteur in 1881 and animals feeding on it may be infected The spores of the tetanus bacillus and the anaerobic bacteria associated with gas gangrene which find their way to the soil especially through the feces of man and animals survive there for long periods of time and on introduction into wounds may germinate and cause disease In the case of organisms existing only in a vegetative phase the capacity to survive outside the animal body is not nearly so great as for spore formers although if vegetative forms are dried rapidly they may remain viable for long periods of time under natural climatic conditions

Numerous studies of the environment have been made in an attempt to explain the epidemiology of hemolytic streptococcal infections of the respiratory tract In places where the disease is endemic living streptococci can be isolated from clothing bedding and other articles as well as from dust and from the air itself The general contamination of the environment was long considered as being of great significance in the spread of streptococcal disease and based on this circumstantial evidence elaborate procedures were set up in military establishments to reduce it Oiling of floors to hold down dust borne streptococci had no influence on the incidence of disease nor did sterilization of air by glycol aerosols or ultraviolet light The studies of Rammelkamp Wannamaker Perry and their colleagues (for review see Rammelkamp 1955 56) have explained why such procedures are ineffective They have presented strong evidence that transmission is direct from man to man and does not appear to occur commonly at a distance through the air or because of dried streptococci present in the dust or on fomites Direct contact with fresh moist secretions of the infected person appears to be the important means of transmission Indeed these investigators have demonstrated that living but dried Group A streptococci present in floor dust are not infectious for man even when instilled into the nasopharynx in large numbers It would appear likely that they are taken up and destroyed by phagocytic cells during the prolonged lag phase before growth can be initiated from the dried state

Likewise pneumococci have been isolated from the environment in places where pneumococcal pneumonia was epidemic and it has been assumed that this environmental contamination is of importance in spread Similarly in the case of epidemic staphylococcal infections in hospitals which constitute such a serious problem at the present time airborne spread is considered as being of great importance although no solid evidence is available to prove it

Unless it is shown otherwise it would ap

TABLE 3 OPERATION OF CHANCE IN PNEUMOCOCCAL CARRIER STATE

Number of carriers of	
1 pneumococcal type	1 317
2 pneumococcal types	200
3 pneumococcal types	27
4 pneumococcal types	4
Ratio of carriers of	
2 types to carriers of 1 type	$\frac{200}{1\,317} = 0\,152$
3 types to carriers of 2 types	$\frac{27}{200} = 0\,135$
4 types to carriers of 3 types	$\frac{4}{27} = 0\,148$

is transmitted from one individual of a species to another of the same species com municable variants alone are involved pre sumably because only these variants would have survived in the original host The size of the inoculum here should play only a small part since most of the bacterial popu lation would consist of communicable vari ants However in transmission from one species of animal to another it is probable that the size of the inoculum is of consider able significance because the conditions nec essary for survival in the new host are likely to be different from those in the original host if the inoculum is large there is more chance of communicable mutants being present than if it is small

Chance In transmission from one host to another of the same species chance may determine largely whether or not the new host becomes a carrier although even in individuals of the same species there may be differences which influence the capacity to become carriers By chance is meant simply the accident of coming in contact with a bacterial species or strain The operation of chance is well illustrated in the communi cability for man of pneumococci (Hodges and MacLeod 1946) From 40 to 70 per cent of normal adult humans carry one or more of the many serologic types of pneumo cocci in the pharynx at any given time some persons carrying as many as 5 distinct types all at once The ratios of carriers of 2 types to 1 type 3 types to 2 types etc as shown in Table 3 are approximately the same indicating that in the main chance has determined how many types of these communicable organisms are carried by an individual

However further analysis of pneumo coccal carriers shows that host factors also operate in determining whether or not an individual will become a carrier of a particular pneumococcal type (MacLeod Hodges Heidelberger and Bernhard 1945) In a population of which half the members were immunized against pneumococcus Types 1 2 5 and 7 it was found that sig nificantly fewer of the immunized men were carriers of these types as compared with the nonimmunes It is apparent therefore that pneumococci are not as communicable to immune persons as to nonimmunes Anal ogous data are not available for other bacteria although a similar state of affairs probably exists for diphtheria bacilli also In this case immunization of approximately half of the susceptible population affords a very considerable measure of protection to the nonimmunized portion as was found true also for pneumococcal infection in a partially immunized population The chain of transmission from one susceptible indi vidual to another appears to be broken by the interposition of immune individuals who are less able to act as carriers In other words the immune status of the individual in the case of pneumococci and probably diphtheria bacilli exerts a powerful influence on communicability

Survival Capacity in Immune Subjects Whereas with certain bacteria the immune individual is less likely to become or remain a carrier than the nonimmune the capacity of many bacterial species to survive in im mune subjects is an important contributing factor in communicability An obvious ex ample is the persistence of typhoid bacilli in the biliary tracts of a proportion of those who have recovered from the disease whence the organisms are discharged into the intes tinal canal and through subsequent fecal contamination of food or water become transmitted to susceptible individuals If the reservoir of infectious agents consisted only of persons actually sick with infection the

pear more reasonable to consider that when bacteria in the dried state are present as general contaminants of the environment this may have no more significance than as a reflection of the fact that disease caused by them is taking place in that environment It should not be assumed that these dried environmental deposits have a significant part to play in spread

Survival in water has an important bearing on communicability of enteric pathogens such as those causing typhoid or paratyphoid fevers dysentery and cholera, all of which may be water borne diseases though not transmitted in this manner exclusively

The ability to survive and multiply in an intermediate host or vector is of prime significance with some microorganisms, of which plague is a good example The plague bacillus causes natural disease in many species of rodents in different parts of the world and is transmitted to man through the bite of various species of fleas which are ectoparasites of the rodents The bacilli are able to multiply and cause disease in the upper portion of the alimentary tract of the fleas which derive their infection from the rodent reservoir The ability of plague bacilli to infect fleas is thus a crucial factor in their communicability *Pasteurella tularense* an organism related to the plague bacillus and the cause of tularemia has its reservoir also in various rodent species and may be carried by arthropods such as ticks and deer flies which feed on the rodents Although in the United States the disease in man is most often acquired during the skinning and the dressing of wild rabbits it is also possible for transmission to occur through the bite of the arthropod vectors

Flies (*Musca domestica*) have long been suspected as being of importance in the transmission of typhoid fever In this instance however the insect occupies a relatively passive role in that the fly is not infected by the typhoid bacillus, nor does it become a permanent carrier of the microorganisms The feet of the fly and other parts of its body surface become contaminated during contact with feces and then the organisms may be transferred mechanically to human food

From this discussion it can be seen that certain of the general properties necessary for communicability of various bacterial species can be defined However as noted earlier little information of a specific nature is available With pathogenic species the communicable organisms carried in the body usually possess the cell structures known to be associated with virulence though this is not uniformly true Pneumococci isolated from normal humans are in the encapsulated that is potentially pathogenic state and the nonencapsulated rough variants are not found On the other hand, hemolytic streptococci isolated from carriers not infrequently have lost the M protein which is known to be concerned in their virulence Therefore these organisms must possess a component or components other than the important M protein which prevent their destruction by the body It can be argued that such avirulent variants, lacking M protein may have no pathogenic significance However, on transmission to a nonimmune host the capacity to produce M protein may be regained because of mutation or possibly as a result of genetic recombination through mechanisms such as transduction or transformation

by the wall of fibrin deposited about many abscesses

Thus anatomic barriers commonly are considered to serve in host defense by limiting penetration and dissemination of microorganisms In some situations however structures within the body appear to permit passage of microbes but not phagocytic cells thus offering havens in which bacteria are protected from usually effective cellular host defense systems Consider for example the pathogenesis of subacute bacterial endocarditis The microbe involved in this severe or even fatal disease is commonly an alpha hemolytic streptococcus otherwise an essentially avirulent organism Alpha streptococci can be introduced into the tissues or even the bloodstream of the normal person with production of little or no disease but in the rare individual with a congenital anomaly of the large blood vessels or with endocardial scars from previous rheumatic fever a few alpha hemolytic streptococci may alight on these abnormal areas and multiply locally to produce the typical lesions called vegetations Microbes disseminated to other tissues from these vegetations are promptly ingested by phagocytes and destroyed but apparently the anatomic arrangements within the vegetation itself afford shelter for the streptococci from host defense mechanisms

Similarly a piece of devitalized bone a sequestrum may provide for staphylococci or other organisms causing osteomyelitis a focus which cannot be penetrated by phagocytic cells because of the microanatomy and such a situation usually leads to persistent infectious disease

Antibody and Phagocytes

Antibody complement and phagocytic cells usually are considered to be the main agencies by which the host rids itself of invading microbes These systems will be discussed in detail in following chapters therefore they are mentioned here only for continuity and for a few general comments Humoral and cellular mechanisms for combating invading microbes or their toxins were discovered at approximately the same time (1890) and together formed the corner stone for the science of immunology For decades a polemic raged between workers led by Von Behring and Pfeiffer who claimed that humoral factors were mainly responsible for host resistence to infectious diseases and scientists under Metchnikoff at the Pasteur Institute who proposed on the contrary that such resistance was due mainly to the action of phagocytic cells Signs of this argument still remain but the debate now has been largely resolved in favor of *both* sides Most types of microbes survive exposure to serum even in the presence of specific antibody Invading bacteria by and large are killed following engulfment by phagocytic cells However phagocytes are able to engulf bacteria efficiently only if serum factors (opsonin and/or antibody) are present Antibodies also clearly play a central role in neutralizing microbial exotoxins Thus effective host resistance requires conjoint action of both humoral and cellular factors

The crucial role of antibodies and of phagocytic cells in resistance to infectious diseases is established beyond doubt The enormous increase in susceptibility to sepsis of persons lacking antibodies (agammaglobulinemia) or lacking phagocytes (agranulocytosis) illustrates clearly the importance of these factors in host defense However much remains to be learned about their precise mechanism of action For instance much is known about the nature of antibodies in terms of their site of formation and chemical properties but little can be said concerning the intimate nature of their action Similarly although we know much about morphologic and other alterations accompanying the killing of bacteria within phagocytes the substance or system responsible for the bactericidal effect remains in doubt or in some cases is completely unknown

The Chemical Microenvironment

Many phenomena indicate that host resistance is based at least in part on factors other than anatomic barriers antibodies and phagocytes One such phenomenon has to do with localization of bacterial infectious diseases Most microbes show a distinct preference for multiplication in a certain tissue or organ of a given host For example streptococci pneumococci and meningococci usually

Host Resistance to Infectious Disease

*In modern times endemic patterns of in*fectious diseases are prevalent in which the causative microbes may be widely disseminated in the population but only rarely produce detectable disease For example fully virulent forms of staphylococci pneumococci meningococci diphtheria and certain clostridia are found frequently in cultures taken from skin mucous membranes or intestinal contents of healthy persons In this setting the critical determinant of disease is not merely exposure or contact but rather the net result of the complex interaction between virulence factors of the microbes and resistance mechanisms of the host

It is our aim in this chapter to consider from the over all point of view some of the general and the specific mechanisms involved in host resistance to bacterial infectious diseases

BASIC MECHANISMS OF HOST RESISTANCE

Anatomic Barriers

Perhaps the most obvious of the host resistance mechanisms is that of barriers posed by skin mucous membranes and other anatomic structures The surface linings of the intestines the upper respiratory tract and the skin in the normal state are swarming with untold numbers of microorganisms whereas beneath these surfaces in the submucosa or the subcutaneous tissue sterile conditions usually prevail microbes on the surface are unable to pass freely through these anatomic barriers

That such barriers do in fact function to protect the host against infectious disease is obvious Everyone knows that skin lacerations commonly are followed by local infectious disease or that a perforated appendix leads to peritonitis However, recent observations indicate that even in the healthy person skin and mucous membranes are penetrated relatively frequently by small numbers of bacteria Minute abrasions accompany such everyday activities as chewing and digesting food brushing teeth shaving or scratching the skin and so forth Apparently tiny breaks in the barrier permit passage of the surface microorganisms for if cultures are taken sufficiently frequently bacteria of the normal intestinal or skin flora can be recovered on occasions from tissues regional lymph nodes and even from the bloodstream (see Hirsch 1960) This invasion by bacteria probably occurs several times daily in everyone but the small numbers of relatively nonvirulent organisms so introduced are eliminated readily by other host defense mechanisms and no disease ensues

In addition to skin and mucosal barriers there exist within the tissues other membranes such as muscle fascia joint synovia or pleural surfaces which act in many instances to localize an infectious process Furthermore in injured or inflammed areas new barriers may be formed as exemplified

centa this localization being in all probability responsible for the cardinal clinical feature of the disease namely abortion (Smith *et al* 1961) The inability of antibodies and phagocytes to reach the fetal placenta cannot explain the unbridled proliferation of brucella organisms at this site for infection of pregnant cattle with various other types of bacteria does not show similar localization Extracts of fetal placenta infected or normal have been found to produce marked stimulation of the growth of brucellae but not of other microbes on artificial media or inside cells in tissue culture Extracts similarly prepared from various other tissues and organs of the same animals have no such action on brucella cultures The active agent in the fetal placenta extracts has now been isolated and identified as erythritol a 4-carbon polyalcohol (Pearce *et al* 1962) This substance is present in fetal placental tissues and fluids but not in various maternal organs or in the fetus itself (Williams *et al* 1962) The evidence thus suggests that trace amounts of this organic chemical which accumulate for reasons unknown in the fetal placenta determine by means of some vitaminlike effect on brucellae to a considerable extent the pathogenesis of infectious abortion in cattle Perhaps similar mechanisms at present totally unknown operate to determine localization of other bacterial infections at other organ or tissue sites

In addition to their action on invading microbes local physicochemical conditions in tissues also undoubtedly influence the function of the classic humoral and cellular host defense agencies In contrast with the situation in guinea pig tuberculosis mentioned above the kidney and especially the renal medulla exhibits striking susceptibility to sepsis in many other laboratory models of infectious diseases as well as in some clinical situations Detailed study of this phenomenon shows as the probable explanation for localization of disease a delayed and grossly deficient phagocytic reaction in the renal medulla (Rocha and Fekety 1964) The high salt concentration of interstitial fluids about the renal tubules might be responsible for impairing phagocytic function both by interfering with mechanisms of chemotaxis and with phagocytosis itself (Chernew and Braude 1962) Ordinary avirulent coliform bacteria also commonly produce infectious disease in the urinary tract Many of these microbes are killed by the combined action of antibody and complement and it has been suggested that the urinary tract manifests unusual susceptibility to sepsis by coliforms because the ammonia normally produced and excreted by the kidneys inactivates essential complement components thus impairing or eliminating completely this humoral defense mechanism (Beeson and Rowley 1959)

THE INFLAMMATORY REACTION

Thus far our discussion has dealt largely with interactions between bacteria and humoral cellular and tissue factors of the normal host In reality the conflict between host and microbe is waged not in normal body tissues or fluids but rather in a tissue environment modified by the conflict itself This modified tissue environment is termed inflammation or the inflammatory reaction (Florey 1962 Spector and Willoughby 1963)

When bacteria are introduced into tissues the irritating effects of the organisms themselves of toxins produced by them or of the procedure of their introduction set in motion a sequence of vascular humoral and cellular alterations The initial change in small blood vessels probably brought on by reflex nerve action is constriction Soon thereafter the vessels relax and enter into a stage of prolonged dilatation Blood flow through the dilated capillaries slows and the endothelial surfaces change so that leukocytes adhere to the vessel walls Vascular permeability increases due probably in the early phase of inflammation to the pharmacologic action of histamine and serotonin released from damaged mast cells in the area Plasma leaks out of the capillaries and the postcapillary venules and is diluted in the tissue juices leading to activation of enzymes and production of substances which alter the vessels so as further to increase their permeability Leukocytes adhering to the endothelium begin to move about and eventually crawl through the capillary wall probably

contact man via the oropharynx yet if disease results from this contact it typically appears in the pharynx with streptococci the lungs with pneumococci and the membranous coverings of the central nervous system with meningococci Many other examples could be given of organ or tissue localization of infectious agents which can not be attributed to the route of exposure This localization can hardly be based primarily on interactions of the bacteria with phagocytes or antibodies, since these are available to any part of the host via the bloodstream Local chemical and physical conditions must differ in various tissues and subtle features of this tissue microenvironment must determine whether or not a particular organism is able to survive and multiply

Biochemical conditions might determine the suitability of a given site for proliferation of bacteria in one of two ways A particular tissue in the host might contain antibacterial substances or conditions which kill or inhibit the microorganism or on the other hand nutrient or vitaminlike substances essential for virulent proliferation of the microbe might be lacking in some tissues but not in others This aspect of host resistance has been but little investigated and in most instances nothing is known about the local physiochemical conditions playing a role in determining the fate of invading bacteria Examples selected from among the few cases in which these microenvironmental agents have been studied will serve to emphasize and illustrate the phenomenon

Many chemical substances found in tissues do in fact exhibit antimicrobial activity under certain circumstances in vitro Long and short-chain fatty acids surface active lipids or proteins basic peptides amines and heme compounds occur in some tissues at concentrations higher than those which kill certain bacteria in the test tube Although studies along these lines are numerous in no instance is there convincing evidence of specific antibacterial action by one of these compounds in vivo (reviewed by Skarnes and Watson 1957 and by Hirsch 1960)

The difficulty of establishing the role of a tissue antibacterial substance in determining the course of an infectious process may be illustrated by the following example The guinea pig is notoriously susceptible to tuberculosis yet the guinea pig kidney exhibits remarkable resistance to this same disease If virulent tubercle bacilli are inoculated directly into the guinea pig kidney the animal develops a progressive fatal illness At autopsy, extensive tuberculosis is found in many organs and tissues but the kidneys regularly appear to be spared even the original renal inoculation site is healed completely (Birkhauser, 1950) With this phenomenon in mind studies have been done attempting to extract from kidney tissue a substance capable of killing or inhibiting tubercle bacilli in culture A crystalline compound with potent antimycobacterial activity has been isolated from the kidney extracts and identified as spermine (Hirsch and Dubos 1952) an organic amine of unknown function distributed widely and variously in tissues Further study in the laboratory on the mechanism of action of spermine on tubercle bacilli has revealed that spermine is in fact not itself directly inhibitory for the organisms rather spermine is degraded by an amine oxidase present in the culture medium and it is some product of this enzymatic attack which then acts to kill or block growth of the microbes (Hirsch 1953) Thu possible antimycobacterial activity of spermine in tissues if it occurs would depend not only on the tissue concentration of spermine but also on the concentration of the amine oxidase and on the presence of physicochemical conditions conducive to the enzymatic reaction and stabilization of the antibacterial product The complexity of this situation has made it impossible to reach definitive conclusions on the role of this system in determining the fate of tubercle bacilli in the infected animal

An example of a tissue chemical agent which favors growth of a specific microbe and may determine the localization of an infectious disease comes from very recent work on the pathogenesis of brucellosis Study of the distribution of viable *Brucella abortus* in various organs and tissues of infected cattle when abortion is imminent shows a striking pattern of the 10^{14} brucellae found in the entire animal approximately 75 per cent are localized in the fetal pla

in most instances understood poorly or not at all but they might act directly or indirectly (1) to alter capacity of the microbe for virulent behavior (2) to affect one or more of the basic host resistance mechanisms—anatomic barriers phagocytic cells humoral factors or local tissue biochemistry or (3) to change the timing or the qualitative or quantitative nature of the inflammatory response

Obviously no attempt can be made here to review thoroughly the broad range of environmental effects and organic disorders which alter more or less resistance to infectious agents and their toxins Rather we shall discuss briefly a few examples to illustrate the wide range of factors which come into play and to point out the general lack of understanding of mechanisms in this field

Hormones and Host Resistance

Hormones secreted by the various endocrine glands serve to regulate a wide variety of physiologic functions Circumstantial and in some cases direct evidence indicates that many of these hormones exert an influence on host resistance mechanisms (reviewed by Kass 1960)

Many observers have commented on relationships between thyroid function and susceptibility to infections The reports are somewhat conflicting with the effects of too much or too little thyroid hormone apparently varying depending on the host and the parasite species studied In experimental tuberculosis in rabbits hyperthyroidism is associated with increased host resistance whereas hypothyroid animals are more susceptible than normal and develop spreading disease (Lurie *et al* 1959a b) On the other hand hyperthyroidism results in lowering of resistance of rats and mice to experimental streptococcal or staphylococcal infections (Reichlin and Glaser 1958 Smith and Dubos 1956)

Epinephrine administered locally say into the skin can interfere profoundly with the host s ability to handle various bacteria injected into the same site (Miles *et al* 1957) The primary action of the hormone in this situation appears to be a protracted vasoconstriction with as a result delay in the development of an inflammatory response and alteration in the tissue microenvironment

Most extensively studied of the hormonal effects on infectious disease is that of the adrenal glucocorticoid hormones These hormones have been used widely during the past decade for treating various diseases Their administration in large doses to man or various animals is regularly accompanied by an impressive increase in susceptibility to invasion by a wide variety of microorganisms including ordinarily avirulent species or latent microbes which are somehow awakened from their state of hibernation to become invasive There is no evidence that cortisone exerts any direct effect on microbes rather it somehow produces alterations in basic host defense mechanisms (reviewed by Germuth 1956 Robinson 1956) An animal under the influence of excess adrenal glucocorticoids exhibits striking suppression of the inflammatory response to a wide variety of noxious agents including invading microbes Cortisone apparently somehow prevents the increased capillary permeability and the leukocyte emigration which underlie inflammation this action undoubtedly accounts at least in part for the lowered host resistance to infection Cortisone and similar steroids also influence carbohydrate and protein metabolism and thus possibly alter the local tissue biochemical environment so as to render it more suitable for microbial proliferation no definitive evidence on this possibility is available Very high levels of cortisone can lead to suppression of antibody formation but this action is probably not primarily responsible for the depressed host resistance (Germuth 1956) Functional capacity of polymorphonuclear leukocytes and of reticuloendothelial macrophages appears not to be significantly altered by excess adrenal hormones although there is some disagreement on this point (see Germuth 1956 Hirsch and Church 1961)

The Influence of Various Diseases on Host Resistance

Various disseminated diseases especially in their terminal phases are associated with a striking increase in susceptibility to infectious agents Patients with leukemia carcinomatosis uremia and other severe illnesses

by penetrating between endothelial cells Through a poorly understood mechanism of attraction called chemotaxis, the leukocytes move toward the invading organisms and if conditions are suitable engulf and destroy them Excessive exudation of fluid into the inflamed area leads to dilatation of lymphatic vessels and increased drainage into regional lymph nodes Microbes caught up in this lymph drainage are filtered in the nodes, being taken up by fixed mononuclear phagocytes which are part of the reticuloendothelial system Fibrinogen in the extravasated fluid may clot particularly at the periphery of the inflamed zone to form a fibrin barrier serving to limit direct spread of the microbes and influencing fluid and cellular exchange between the inflammatory area and the surrounding normal tissue

Thus when bacteria gain access to tissues a race of sorts ensues The outcome depends in no small measure on the rapidity and the nature of the inflammatory reaction which provides a mechanism for the controlled escape of humoral and cellular resistance agencies from the bloodstream so that they may establish contact with the invading microbes

The physicochemical features of the inflammatory site remain to be studied thoroughly but they differ in many regards from those of normal tissue Blood stasis, influx of phagocytic cells with glycolytic metabolism growth of the microbes themselves, damage and even death of host cells produce in the inflamed zone a slightly acid pH a lowered oxygen tension retention of CO accumulation of lactic acid and undoubtedly numerous other changes (Dubos 1954 1955) Some of these biochemical alterations may act, for instance by damaging blood vessels to perpetuate or increase the inflammatory reaction they also undoubtedly affect both the capacity of the microbes to thrive and the functional efficiency of classic humoral and cellular defense systems

An inflammatory reaction which is overly vigorous or uncontrolled multiplication of the bacteria may lead to tissue necrosis with further changes in the microenvironment in which the battle is fought Of course tissue necrosis is not the result to be desired by the host but in at least some situations necrosis and the attendant local biochemical changes may serve to limit further multiplication of the parasite and act ultimately as a host defense mechanism Consider for instance microscopic features of the typical lesion of tuberculosis the tubercle (Canetti 1955) The center of such a lesion is composed of structureless partially autolysed necrotic tissue, and surrounding this central core is a cuff of viable tissue heavily vascularized and infiltrated with phagocytic cells Tubercle bacilli die off and disappear from the central necrotic area whereas they continue to thrive in the surrounding inflamed living tissue Thus is presented the paradoxical situation of continued growth of the invading microbes in the area containing an abundant supply of the classic host defense systems humoral and cellular, and death of the organisms in the avascular, acellular zone[1]

So little is known about the chemical composition of necrotic tissue that no definitive statements are possible as to the physicochemical components which might exert antimicrobial effects therein Accumulation of fatty acids porphyrins and amines liberation of basic proteins and peptides and release of antibacterial substances from disrupted phagocytic cells may well be responsible at least in part for suppressing microbial growth in such areas (see Hirsch 1960) Synergists and antagonists for these antibacterial substances from tissue are probably always present or readily available in an infected area and no doubt determine in no small measure whether or not in vivo activity can occur Our knowledge of the subtle and dynamic biochemical aspects of the local site of the host parasite encounter is primitive indeed yet it is likely that just these aspects determine directly or indirectly the fate of the invading microbes

FACTORS THAT ALTER HOST RESISTANCE TO INFECTION

Many disease processes or environmental factors result in disturbances of general host physiology which are associated with altered resistance to infectious diseases The precise means by which these abnormal physiologic states influence the host parasite conflict are

of the intestinal flora (Dubos and Schaedler 1962) Even severe degrees of malnutrition do not significantly impair antibody formation or grossly interfere with phagocyte performance or the inflammatory reaction

The widespread notion that better than average nutrition leads to better than average resistance to infections appears to be a misconception There is little evidence that supplementation of ordinary diets with vitamins or other factors has any effect on host resistance (see Scrimshaw *et al* 1959)

In fact in a few instances dietary deficiencies seem to be associated with increased ability to ward off microbial invaders An example of such a phenomenon is the resistance to malaria of rats or monkeys on a milk diet When this association was first noted it was assumed that milk might contain some resistance factor for malaria Further study has shown that the milk diet is deficient in a vitaminlike substance para aminobenzoic acid required for growth of malaria parasites Resistance while on the milk diet is due to this deficiency for supplementation with the acid promptly renders the animals susceptible to malaria infections (Hawking 1954)

The Influence of Weather on Infectious Diseases

Most infectious diseases display a rather regular pattern of seasonal incidence—streptococcal pharyngitis is most common in late winter or early spring viral influenza occurs most frequently in early winter infantile diarrhea due to coliform organisms prevails in the summer etc These seasonal patterns are commonly explained by prevalence of insect vectors by variations in sanitary conditions by crowding of the host or by effects of temperature humidity and sunlight on survival of the microbe outside the host However for many infectious diseases seasonal patterns are completely unexplained

Such seasonal fluctuations may also be due at least in part to effects of the weather on host physiology and resistance mechanisms as is indicated by the following example In the course of studies on streptococcal infection of mice in an aerosol chamber Coburn and associates (1957) noted that the animals developed severe often fatal diseases when the experiments were done in winter months whereas during the summer the mice showed no illness following similar exposure To study the phenomenon further a large batch of virulent streptococci was cultured and then divided into small lots which were preserved by freeze drying so that essentially identical bacteria could be used for the inoculations over the course of 2 or more years Then mice were exposed to the streptococcal aerosol under standard conditions every month Cultures taken from the animals after exposure established that similar numbers of viable bacteria were introduced in all seasons thus contact between mice and the streptococcal bacteria was the same Yet over the period of observation the mice so exposed developed streptococcal infectious disease often fatal only during winter and spring months In the summer and the fall no disease resulted These results thus indicate that in this particular model season or weather may influence the occurrence of infectious disease by affecting the physiology of the host somehow to alter suceptibility to sepsis

Similarly recent studies on experimental transmission of viral influenza in mice also suggest that seasonal factors may somehow influence host resistance (Schulman and Kilbourne 1963)

Many different types of environmental factors are included under the terms weather or season and few studies have been done attempting to relate isolated meteorologic factors and susceptibility to infectious diseases Temperature may well play a role in this regard for animals exposed to cold exhibit impaired resistance to salmonellosis and staphylococcal infections (Miraglia and Berry 1962)

Role of the Normal Flora in Host Resistance

Host resistance to sepsis is influenced by the nature of the normal microbial flora As stated earlier skin mucous membranes of the upper respiratory tract and intestines are swarming with myriads of microbes living in peaceful coexistence with the host When this normal flora is eliminated or altered drastically by germ free technic or by administration of antimicrobial drugs striking

often develop sepsis the invading microbe may be one of the avirulent members of the indigenous flora Information is not available on the precise alterations in host resistance mechanisms in this setting

Persons afflicted with diabetes mellitus are unusually prone to develop cellulitis or boils and seem to exhibit lowered resistance to infectious diseases in general The resistance to experimental fungal infections of animals made diabetic by administration of alloxan is depressed only if their diabetes is uncon trolled to the extent that acidosis develops Detailed investigation of the host parasite interaction in these diabetic and acidotic animals shows as a possible basis for their increased susceptibility a delayed and grossly deficient influx of phagocytic cells into the challenge site (Sheldon and Bauer 1959) Metabolic derangements in diabetes doubtless also lead to changes in local tissue chemistry which may well influence the course of incipient infectious disease

Disturbance of host resistance is by no means limited to generalized or severe dis eases Local abnormalities sometimes exert a profound effect on pathogenesis of infec tions As discussed in an earlier section an endocardial scar resulting from an attack of rheumatic fever often becomes the site of local invasion by usually benign microbes with resulting production of the serious disease subacute bacterial endocarditis Other local abnormalities also can result in ineffective host resistance For example ob struction to the flow of any drainage system —urinary tract respiratory tree bile canals etc —is almost uniformly associated with invasion of the obstructed system by bacteria of the normal flora and production of severe and often persistent infectious disease The precise mechanisms which account for local paralysis of host defense in this setting are not clearly established altered local physical and chemical conditions which result from obstruction probably affect both the para site and the host response

Disease caused by one microbial agent may also influence host resistance to another unrelated microorganism The striking in crease in susceptibility to bacterial pneu monia which follows an attack of viral influenza exemplifies this phenomenon Mechanisms underlying this relationship are not well understood

Host resistance may also be altered strik ingly by the therapy administered for other diseases As mentioned above multiple host resistance agencies are affected by cortisone and related steroids Increasing use is now being made of certain antimetabolites and alkylating drugs for cancer chemotherapy and for suppression of transplantation immunity these drugs often impair both cellular and humoral resistance mechanisms and patients who receive them show unusual susceptibility to infectious diseases Similar or even more marked impairment of resistance to sepsis is seen in persons or animals exposed to large doses of gamma or x irradiation which result in breakdown in anatomic barriers cessation of phagocyte production and paralysis of antibody formation (Miller 1956)

Nutrition and Infection

Long before the modern microbial era it was recognized that a relationship existed between famine and epidemic contagious disease History continues to record this relationship during World War II striking outbreaks of infectious disease occurred among prisoners-of war deprived of adequate food

The literature on relationships between nutrition and infection is voluminous and disconcertingly inconclusive (reviewed by Schneider 1946 Scrimshaw et al 1959, Dubos and Schaedler 1959) In some in stances the diet has important effects on the invading microbe and on the mechanisms of the host response however these effects often vary depending on the particular microbe and host and are intimately inter woven with other aspects of host physiology

Even a relatively short period of starva tion renders experimental animals unusually susceptible to microbial challenge Imbalance in the diet and especially shortage of ade quate protein nutrients can lead to similar effects (see Dubos and Schaedler 1959) Little is known about the precise chain of events involved in depression of resistance by these nutritional disturbances The effect may be a direct one or in some instances it may operate through associated disturb ances e g hormonal changes or alteration

changes take place in susceptibility to certain infectious diseases For example bacillary dysentery cannot be produced in ordinary guinea pigs even when large doses of virulent shigella organisms are given However ad ministration of the same microbes to germ free guinea pigs gives rise to fatal ulcerative enteritis (Sprintz *et al*, 1961) The increased incidence of staphylococcal entero colitis and of moniliasis during the course of long term therapy of persons with broad spectrum antibiotics is an example of the same phenomenon from the field of clinical medicine

Strictly speaking the normal flora cannot be classified as a host resistance mechanism since the microbes are outsiders living with but not part of the host Their role in deter mining pathogenesis of infectious diseases is nevertheless important How does the normal floral protect the host from potentially harm ful bacteria?

The most logical explanation would in voke a kind of interference As an analogy a dense healthy stand of good grass is relatively resistant to growth of airborne weed seeds alighting upon it whereas a barren field provides a fertile area for un controlled growth of weeds The skin or the mucosal surfaces of mammals perhaps pro vide sufficient nutrients for survival of only a finite concentration of microorganisms If the normal flora effectively utilizes this supply of nutrients invaders find it difficult or im possible to establish a foothold Or an alter native explanation would involve production by the normal flora of substances (antibi otics) or conditions (acidity low oxygen tension etc) inhibitory for foreign microbes attempting to establish residence in the area

Some evidence suggests furthermore that the normal flora affects resistance of the host to infection at sites far removed from the habitat of the flora itself Thus it is also possible and even likely that the normal flora exerts a significant influence on general host physiology, perhaps by providing vita mins, by exposing the host continuously to small doses of endotoxins or by affecting directly or indirectly *antibody producing* systems or turnover of phagocytic cells These physiologic effects might well be re flected in alterations in the ability of the host to handle a given challenge of infectious material

CONCLUSION

Pathogenesis of infectious diseases seems at first glance to be relatively simple and well understood The environment in which man lives is swarming with microbes of all sorts some of these are capable of virulent be havior based on specific structures which they possess or poisons which they produce To ward off the challenge of these potentially virulent bacteria man calls into play his defense mechanisms anatomic barriers phagocytic cells and antibodies

Our purpose in this chapter has been to examine anew the mechanisms of resistance to infectious disorders in the light of modern knowledge and concepts emphasizing the unknown as well as the known These mech anisms are multiple are in many instances still understood poorly or not at all and probably differ from microbe to microbe from person to person and from time to time Host resistance is determined not only by antibodies and phagocytes but also by a myriad of subtle factors some local some general and some entirely separate from the host itself

The pathogenesis of infectious diseases in many ways illustrates well the infinite complexity of biologic systems with living things existing in a state of delicate balance under the constant influence of interactions between themselves and their environment

The Role of Antibody, Complement and Other Humoral Factors in Host Resistance to Infections

INTRODUCTION

Host defense to infectious agents is a complex biologic process requiring participation of cells as well as humoral factors In this chapter we shall deal exclusively with the nature and the function of humoral factors It is to be emphasized that separate treatment of the humoral aspect represents an abstraction from the actual biologic phenomenon in the living organisms cellular and humoral defense mechanisms are interdependent and intimately interwoven

Serum factors contribute to host defense essentially in three ways neutralization of bacterial toxins and viruses destruction of microorganisms and promotion of phagocytosis The factors primarily responsible for these effects are antibody complement and opsonin Initially these terms designated merely serologic activities Today at least some of these activities can be ascribed to discrete serum protein entities which are now being subjected to thorough physical and chemical analysis The achievements of recent years encourage the belief that it will be possible in the foreseeable future to describe the humoral mechanisms of host defense entirely in terms of the underlying molecular events Wherever feasible the molecular aspect will be preferred to the serologic throughout the following discussion

HISTORY

The chemical approach to problems of immunity was introduced by Paul Ehrlich He believed so firmly in the chemical mode of action of antibody and complement that he was led to attempt imitation of their biologic activity with the aid of compounds synthesized in the laboratory When Ehrlich began his work on the mechanism of immunity the cellular theory of immunity was well established Metchnikoff had drawn wide attention to the crucial role of the migrating phagocytic cell in host defense against invading microorganisms He regarded the phagocytic cell as solely responsible for the phenomenon of natural immunity and as the primary force in acquired immunity Nutall s demonstration of bactericidal power of serum was attributed by Metchnikoff to an artefact He ascribed it to the release of bactericidal substances from leukocytes on their disintegration in vitro That phagocytosis required the presence of serum was in his opinion due to the sustaining effect of serum on cell function (Metchnikoff 1905)

During the latter part of the last century theories of biology and medicine were based on cellular phenomena Humor was a notion which was colored and burdened with the memory of obsolete speculations Therefore theories invoking the body fluids met with

The Role of Antibody, Complement and Other Humoral Factors in Host Resistance to Infections

INTRODUCTION

Host defense to infectious agents is a complex biologic process requiring participation of cells as well as humoral factors In this chapter we shall deal exclusively with the nature and the function of humoral factors It is to be emphasized that separate treatment of the humoral aspect represents an abstraction from the actual biologic phenomenon in the living organisms cellular and humoral defense mechanisms are interdependent and intimately interwoven.

Serum factors contribute to host defense essentially in three ways neutralization of bacterial toxins and viruses destruction of microorganisms and promotion of phagocytosis The factors primarily responsible for these effects are antibody complement and opsonin Initially these terms designated merely serologic activities Today at least some of these activities can be ascribed to discrete serum protein entities which are now being subjected to thorough physical and chemical analysis The achievements of recent years encourage the belief that it will be possible in the foreseeable future to describe the humoral mechanisms of host defense entirely in terms of the underlying molecular events Wherever feasible the molecular aspect will be preferred to the serologic throughout the following discussion

HISTORY

The chemical approach to problems of immunity was introduced by Paul Ehrlich He believed so firmly in the chemical mode of action of antibody and complement that he was led to attempt imitation of their biologic activity with the aid of compounds synthesized in the laboratory When Ehrlich began his work on the mechanism of immunity the cellular theory of immunity was well established Metchnikoff had drawn wide attention to the crucial role of the migrating phagocytic cell in host defense against invading microorganisms He regarded the phagocytic cell as solely responsible for the phenomenon of natural immunity and as the primary force in acquired immunity Nutall s demonstration of bactericidal power of serum was attributed by Metchnikoff to an artefact He ascribed it to the release of bactericidal substances from leukocytes on their disintegration in vitro That phagocytosis required the presence of serum was in his opinion due to the sustaining effect of serum on cell function (Metchnikoff 1905)

During the latter part of the last century theories of biology and medicine were based on cellular phenomena Humor was a notion which was colored and burdened with the memory of obsolete speculations Therefore theories invoking the body fluids met with

suspicion While cells and the phagocytic process could be comprehended easily by *microscopic observation* there was no microscope at hand to visualize serum constituents and to facilitate the understanding of their function Nevertheless the basic concepts of humoral immunology were evolved then and they have retained their validity to the present Due to a complete lack of information regarding the composition of serum the terminology created by the early students of antibody and complement is often romantic and awkward and tends to obscure the extent of their contribution

Soon after Nutall s discovery of the bactericidal power of serum Pfeiffer (1903) found *bacteriolytic activity* to be increased in the serum of animals that had survived a bacterial infection The serum would lyse only those bacteria with which the animal had been infected The activity could be transferred with cell free serum to a non immune recipient It was thermostable and this property distinguished it from the heat labile bactericidal principle which Buchner attributed to an enzyme in serum Thus there appeared to be two humoral principles and it was soon recognized that both were required for bacteriolysis The heat stable factor with specificity for microorganisms was later designated as antibody and the heat labile enzymelike substance as complement It was Ehrlich (1906) who formulated the final concept of immune cytolysis according to which antibody combines by means of a specific combining site with a receptor on the cell surface Complement secondarily attaches itself to a receptor site on the antibody molecule and thereby is enabled to execute its damaging effect on the cell membrane

Bordet s discovery of immune hemolysis greatly facilitated the study of serum factors with cytolytic activity It provided a simpler experimental system and a means for precise quantitation of the effect of antibody and complement More importantly it led to the realization that immune cytolysis is not confined to microorganisms but concerns cells in general thus forming the basis for the concept developed later that antibody and complement not only participate in host defense against pathogenic microbes but also against heterologous and isologous cells transferred from another organism This view now has been broadened even further to include the possibility that complement might be capable of damaging autologous cells in diseases with an immunologic basis

The key idea in the young field of humoral immunology was that of the specificity of antibodies In 1890 Emil von Behring discovered that animals which had been infected with diphtheria produced antibody to diphtheria toxin The antibody was able to confer immunity on another animal which had not been previously exposed to either the microorganism or the toxin and the protective effect was entirely specific Almost simultaneously Ehrlich carried out experiments with the plant poisons ricin and abrin and demonstrated that an antiricin antibody could neutralize the effect of ricin but not of abrin and vice versa In defining *antibody specificity* Ehrlich resorted to the principles of enzymology Emil Fischer had compared the fit between enzyme and substrate with the relationship between key and lock It was this highly specific relationship that Ehrlich visualized to exist between antibody and antigen The subsequent work of Landsteiner and that of Avery and his collaborators revealed how sensitive a tool an antibody is for the detection of minute differences in the structure of antigenic determinants

The earliest phase of chemical immunology began when it became possible to study antigen antibody reactions in vitro Since the plant poisons ricin and abrin have the ability to agglutinate the red cells of certain species inhibition of agglutination could be used as a measure of *neutralization of toxin* by antitoxin Using this method Ehrlich established a quantitative relation between the dose of antitoxin and the degree of neutralization He also demonstrated with these experiments that the neutralization of toxin is a purely humoral process which does not require cells

The term neutralization was chosen by Ehrlich because he firmly believed that the interaction between antigen and antibody was basically similar to an acid base reaction Arrhenius adopted this view and developed it by applying the law of mass action to the theoretical treatment of immune complexes Like other chemical reactions the union of

antigen and antibody was considered to be reversible and the equilibrium dependent on the concentrations of the reactants and the reaction product Arrhenius thus introduced methods and principles of physical chemistry into immunology Incidentally he was the first to speak of the science of immuno chemistry

After the basic concepts of chemical immunology had been developed during the latter part of the last century interest turned to the elucidation of the nature of antibody and complement and of the structure of anti genic determinants This new period of activity began in the mid twenties and is still continuing

ANTIBODY

Antibodies are serum proteins which are uniquely endowed with an affinity for a mul titude of naturally occurring and synthetic substances called antigens Each antibody molecule carries specificity for only one anti genic group In general antibody molecules possess two sites capable of combining with antigen By virtue of their combining sites antibodies can give rise to the formation of soluble antigen antibody complexes insol uble immune precipitates and to aggluti na tion of cells and particles if antigen is bound to their surface Antibodies themselves anti genic belong to the immunologically defined family of γ globulins

Localization of Antibody Activity in γ Globulins

The proteins of serum may be separated in an electric field into 4 major fractions of different electrochemical properties In the order of their mobility at pH 8 6 they are designated albumin α β and γ globulin the last being the slowest migrating fraction To determine the relation of the eletropho retic fractions to antibody activity of serum Tiselius and Kabat (1939) compared the patterns of normal sera with those of hy perimmune sera Hyperimmune sera differed strikingly from normal controls in that the γ globulin fraction was conspicuously in creased On absorption with homologous antigen the γ globulin concentration in im mune sera was reduced to a normal level With these observations Tiselius and Kabat established that antibody activity is a function of the γ globulin molecule Today the terms antibody protein and γ globulin are often used synonymously and it is thought prob able that all γ globulin occurring in normal serum represents specific antibody This view is strengthened by observations of animals raised in a germ free environment γ globulin levels in such animals are often as low as 10 per cent of the normal and they rise rapidly on exposure of the animals to an ordinary environment (Gustafsson and Laurell 1959)

Since the early days of electrophoretic investigation when γ globulin was defined by the physical chemist as the slowest migrating fraction of serum the story of γ globulin has become immensely complex This devel opment began when immunochemists dis covered that small amounts of protein closely related to γ globulin are found with great regularity in the β and even the α globulin region of the electrophoretic spectrum (Slater 1955 Williams and Grabar 1955) Today therefore an immunochemical defini tion is preferred according to which all proteins that are recognized by antibody to classic γ globulin are members of the γ globulin family irrespective of electropho retic mobility This group of related proteins is comprised of 7S γ globulin 19S γ globulin and β_A globulin including their pathologic counterparts the myeloma proteins and the macroglobulins of the Waldenstrom type The low molecular weight γ_L globulin of serum and normal and pathologic urine also belongs to this group With identification of the β proteins and the 19S proteins as γ globulins the question arose whether these proteins also have antibody activity

There is no doubt that 19S γ globulin possesses antibody activity In fact, the earliest studies of hydrodynamic aspects of purified antibodies disclosed the occurrence of active 19S components in hyperimmune sera (Heidelberger and Pedersen 1937 Kabat 1939) Later certain antibodies of human origin such as the Wassermann anti body and the antibody to the somatic O anti gen of the typhoid bacillus were found to be of high molecular weight (Davis *et al* 1945 Deutsch *et al* 1946) In recent years Kun

TABLE 1 PROPERTIES OF THE HUMAN GAMMA GLOBULINS

	7S γ GLOBULIN	19S γ GLOBULIN	β_{2A} GLOBULIN	γ_L GLOBULIN

Sedimentation coefficient	7S	19S	7 15S	1S
Molecular weight	160 000	1 000 000	150 000 600 000	25 000
Carbohydrate content	2 6%	10 5%	10%	0%
Antibody activity	present	present	present	absent
Pathologic counterpart	γ Myeloma protein	Waldenstrom s macroglobulin	β_{2A} Myeloma protein	Bence Jones protein

kel (1960) has studied a larger series of human antibodies and has demonstrated conclusively the existence of an entire class of antibodies of high molecular weight To it belong certain isoagglutinins and antibodies against the M the N and the P antigens of human red cells normal and pathologic cold agglutinins and heterophile antibodies as well as certain autoantibodies occurring in patients with lupus erythematosus and similar diseases Rheumatoid factors are also 19S antibodies (Kunkel *et al*, 1959) they are of particular interest since they exhibit a high degree of specificity for autologous and isologous γ globulin and have permitted the discovery of hereditary γ globulin groups

Much more difficult to answer has been the question whether β_{2A} globulin contains antibody activity Some evidence suggests the occurrence of antibodies against bacteria and viruses (Schultze 1959) and of reaginic activity (Heremans *et al* 1962) in this fraction There has also been the suggestion that a new ultracentrifugal species of antibodies (9 15S) might be related to β_A globulin primarily because their sedimentation behavior resembles that of β_A polymers (Rockey and Kunkel 1962) Using highly specific antiserum to β_A globulin Fireman *et al* (1963) succeeded in absorbing β_{2A} globulin from human serum virtually without affecting the concentration of the other two γ globulins When this procedure was applied to sera containing skin sensitizing antibodies to ragweed pollen the reaginic activity was eliminated completely together with β_A-globulin These elegant experiments established conclusively that antibody activity does reside in this fraction Thus all 3 major γ globulins have been shown to have antibody function

TYPES OF γ GLOBULIN AND THEIR PROPERTIES

There are 4 principle types of γ globulin which are related to each other through common antigenic determinants In terms of molecular structure the 4 γ globulins share certain polypeptide chains but differ with respect to others

7S γ Globulin represents approximately 10 per cent of total serum protein Its molecular weight is in the vicinity of 160 000 The predominant N terminal amino acids are aspartic and glutamic acid A carbohydrate moiety accounts for 2 6 per cent of the weight of the molecule and is composed of galactose mannose fucose hexosamine and neuraminic acid While 7S γ globulin appears to be quite homogeneous when examined in the ultracentrifuge it exhibits a perplexing heterogeneity on electrophoresis The electrophoretic mobility spectrum ranges from -0.5 to -3×10^{-5} cm² sec⁻¹ V⁻¹ Approximately 80 per cent of the protein behaves electrophoretically as classic γ globulin The rest has mobility values of β and α globulins (Slater 1955 Williams and Grabar, 1955) This fact was first revealed with the aid of the immunoelectrophoretic method and prompted definition of γ globulin in terms of antigenic rather than electrochemical properties

The wide electrophoretic distribution of 7S γ globulin is due to the presence in this fraction of a large number of discrete molecular species each presumably derived from an individual clone of plasma cells That individual plasma cell clones are able to produce γ globulins with an extremely narrow mobility distribution is apparent from the behavior of myeloma proteins and of certain

antibodies (Kunkel et al 1963) They may give rise to unusually sharp protein peaks Originally the sharpness of their peaks as well as some other features were believed to be reflections of an abnormal protein structure but present evidence suggests that myeloma proteins are only abnormal elevations of otherwise normal individual species of γ-globulin In many recent studies therefore they have been utilized to obtain information on monoclonal γ globulins which for technical reasons could not be obtained on normal serum As will be seen below myeloma proteins and highly purified antibodies resemble each other in certain structural features Therefore it is tempting to relate the molecular heterogeneity of 7S γ globulin to the multitude of different antibody specificities which reside in this protein Different specificities require differences in combining regions which in turn may produce dissimilarities in over all molecular characteristics On the other hand molecular heterogeneity may be an expression of complexity of the cell population from which the protein originated

19S γ Globulin This protein was not clearly recognized as a separate entity until it was isolated and shown to be chemically different from 7S γ globulin (Muller Eberhard *et al* 1956) It contains a carbohydrate moiety which accounts for more than 10 per cent of the molecule and is 4 times larger than that of 7S γ globulin The individual carbohydrate constituents are the same as in 7S γ globulin but their relative proportions differ The protein has a molecular weight of 1 million and an electrophoretic mobility intermediate to γ and β globulin

The most interesting feature of this protein is that it is composed of a number of subunits probably 6 which are held together by disulfide bonds By treating 19S γ globulin with disulfide bond-cleaving reagents Deutsch and Morton (1957) were able to dissociate it into 7S subunits With this discovery they called attention to the significance of S S bonds for the structure of γ globulin and stimulated studies concerned with the chemical dissociation of γ globulin into polypeptide chains The role of intramolecular S S bonds in the activity of 19S antibodies is revealed by the effect of reduction and reoxidation Reduction with mercaptoethanol is accompanied by complete loss of activity (Fudenberg and Kunkel 1957) subsequent reoxidation leads to reactivation (Kunkel *et al* 1961)

The pathologic counterparts of 19S γ globulin are the macroglobulins of the Waldenstrom type If the pathologic γ globulins represent unusually elevated normal proteins then it ought to be possible to find antibody activity associated with at least some of them While such observations have not been reported for myeloma proteins with one possible exception (Waldenstrom 1961) antibody activities have definitely been found for some of the Waldenstrom macroglobulins (MacKay 1959 Kritzman *et al* 1961)

β_{A} Globulin This serum component was discovered in immunoelectrophoretic studies by Grabar and Williams (1953) It migrates in the region between γ and β-globulin The carbohydrate content of the purified material is approximately 10 per cent (Heremans 1960) It occurs in several molecular species the major component has an s rate of 7S the minor components of 9 15S The faster sedimenting material can be dissociated into 7S units by reduction with mercaptoethanol (Fahey 1961)

γ_L Globulin To the 3 categories of γ globulins discussed so far a 4th one has been added recently Evidence for its existence was first obtained when a γ globulin of low molecular weight was isolated from normal human urine (Webb *et al* 1958 Franklin 1959) Originally it was thought to be a breakdown product derived from normal serum γ globulin but now it is considered to arise from *de novo* synthesis Interest in γ_L globulin was stimulated considerably when Berggård (1961) demonstrated its occurrence in normal human plasma Its concentration in plasma is so low that it can be recognized only after separation from the bulk of the serum proteins by ultrafiltration and subsequent concentration The best estimates indicate a molecular weight of 25 000 which is surprisingly low for a serum protein therefore it was named γ_L globulin (L stands for low molecular weight) Th immunologic identity of γ_L of plasma and of urine has been established (Berggård 1961)

γ Globulins of low molecular weight are known to occur in the urine of patients with

multiple myeloma. Such patients excrete large amounts of the so-called Bence Jones protein which is also characterized by peculiar thermosolubility properties Bence-Jones proteins precipitate at temperatures between 50 and 60 C and become soluble again at higher temperatures These proteins have been identified with a well characterized species of polypeptide chains the so-called L chains, of normal and pathologic γ globulins (Edelman and Gally 1962) Since γ_L globulin was found to resemble L chains in several important respects (Berggard and Edelman, 1963), it is now regarded as the normal counterpart of Bence Jones proteins

Present evidence indicates that the isolated light polypeptide chains of antibodies do not have antibody activity (see below) Inasmuch as γ_L-globulin consists of light chains antibody activity would not be expected to reside therein Contrary to this reasoning one group of investigators (Remington *et al* 1962) has reported poliovirus neutralizing activity and specificity to tetanus toxin to be present in urinary γ_L globulin of an immunized person

Genetic Types of Human γ Globulin

The existence of genetic types of γ globulin was discovered by Grubb and Laurell (1956) To date 7 genetic factors are known The 4 major ones are called Gm (a) Gm(b) Inv(a) and Inv(b) They are determined by genes present at 2 loci the Gm and the Inv The genetic properties are detected by a method utilizing rheumatoid factors which have anti Gm and anti Inv specificity Gm(a) and Gm(b) sites are found only in 7S γ globulin They are absent from 19S γ globulin β_A globulin and Bence Jones proteins By contrast the Inv character is a property of all 4 γ globulins It follows from the distribution of the genetic sites that the Inv character must be located on a type of polypeptide chain which occurs in all 4 proteins whereas the Gm site should be located in a region of the molecule which is peculiar to 7S γ globulin Indeed it has been possible to localize the Inv and the Gm properties to different parts of the 7S γ globulin molecule The Inv property is located in the so-called S-fragment and the Gm site in the F fragment (Harboe *et al* 1962 Franklin *et al* 1962) Only the F fragment is unique to 7S γ globulin whereas the S fragment contains groups that are common to the entire γ globulin family

Structure of γ Globulin

Elucidation of the structure of a protein with a molecular weight of 160 000 is a formidable task In the case of γ globulin this task is particularly difficult owing to the existence of a bewildering microheterogeneity within the protein Isolation from normal serum of homogeneous species of γ globulin or of antibody directed to a single antigenic determinant is not possible at present In spite of these difficulties the problem of γ globulin structure is being pursued actively in a number of laboratories Interest centers on the question of what constitutes the chemical basis of antibody specificity Is there a region in the molecule with a high degree of initial flexibility which is potentially capable of assuming many different conformations? Or is there a segment which varies in amino acid composition from one antibody to another? In short is specificity determined by primary or by secondary and tertiary structure? In pursuing these questions several groups of investigators recently have succeeded in elucidating some general structural features of the γ globulin molecule The over all objective has been separation of the molecule into structural and functional subunits Two methods have been used hydrolysis with proteolytic enzymes and chemical dissociation

Fragmentation by Enzymatic Hydrolysis In 1958 Porter separated papain-digested rabbit antibody on carboxymethyl cellulose and obtained 3 distinct products Further work (Porter 1959 Nisonoff *et al* 1960 Palmer *et al*, 1962) yielded the following information Treatment of rabbit 7S antibody with papain in the presence of cysteine produces 3 fragments called I II and III Fragments I and II have a molecular weight of 50,000 They are highly similar or even identical with each other for a given antibody molecule and cannot be separated Fragment III has a molecular weight of 80 000 and can be crystallized It differs from the other 2 pieces in many respects Piece I and piece II each contain one antibody-combining site

Being univalent they are unable to precipitate homologous antigen Yet they are capable of inhibiting specific precipitation by intact antibody Piece III is entirely devoid of specific antibody activity but it is responsible for placental transfer of the intact 7S molecule and for its ability to fix to skin which is a prerequisite for cutaneous anaphylaxis (Ovary *et al* 1961) In the undegraded molecule pieces I and II are linked to each other by 1 rather labile disulfide bond and both are linked to piece III by peptide bonds If pepsin is used for degradation instead of papain activated by cysteine the labile disulfide bond is not split A bivalent 5S antibody results which consists of 2 univalent pieces held together by 1 disulfide bridge Fragment III becomes dialyzable under these conditions

Enzymatic degradation has also been applied to the study of the antigenic structure of human γ globulin (Edelman *et al* 1960 Franklin and Stanworth 1961) By immunoelectrophoresis 2 antigenically distinct fractions can be identified One migrates more slowly than 7S γ globulin and therefore is called the S fragment The other migrates faster and accordingly is designated the F fragment The S fragment is analogous to pieces I and II of rabbit γ globulin it contains univalent antibody activity (Morse and Heremans 1962) The F fragment corresponds to piece III There is no immunologic cross reaction between the S- and the F fragments

This new approach has led to a better understanding of the structural basis for the well known immunologic interrelationship between the various γ globulins The cross reacting determinants are confined entirely to the S fragment and the F fragment is unique for 7S γ globulin (Franklin and Stanworth 1961) Thus the chemical groups that occur in all major classes of γ globulin have been identified as a part of the fragment which carries the antibody-combining site

Fragmentation into Polypeptide Chains Following the discovery of the critical role played by disulfide bonds in the structure of 19S γ globulin (Deutsch and Morton 1957) Edelman (1959) demonstrated their significance for the structure of 7S γ globulin Treatment of the protein in strong urea solutions with reducing agents resulted in diminution of the molecular weight from 160 000 to 50 000 The concomitant appearance of 14 to 18 sulfhydryl groups per molecule indicated that 7 to 9 disulfide bonds were broken in the process Edelman interpreted these findings to indicate that the 7S molecule is composed of several polypeptide chains and that these chains are interlocked by S S bonds and weaker forces

Further evidence for the validity of this hypothesis came from experiments employing starch gel electrophoresis (Edelman and Poulik 1961) Two different categories of fragments were detected in reduced and alkylated 7S γ globulins One category comprised electrophoretically fast migrating units which later turned out to be of very low molecular weight they were called light (L) chains The other consisted of more slowly migrating and heavier fragments they were termed heavy (H) chains The pattern of reduced whole γ globulin was not very revealing However the patterns of reduced myeloma proteins and antibodies disclosed the presence of only a small number of chains in a given protein Most interestingly starch gel patterns obtained on reduced individual γ globulins differed from one protein to the other leading to the impression that the individual species of 7S molecules contained similar or identical H-chains but varied in their set of L-chains Exactly how many chains make up one γ globulin molecule was difficult to ascertain Quantitation was seriously hampered because of insolubility of the dissociated chains outside strong urea solutions

Further progress was afforded by the development of a method which allowed preparation of the chains in a soluble form without the use of urea (Fleischman *et al* 1963) It was now possible to separate H and L-chains by a simple gel filtration process to quantitate their relative proportions and to determine the molecular weights Utilizing the body of accumulated information Porter (1962) proposed a model for the structure of rabbit 7S γ globulin (Fig 1) He envisions one molecule to consist of 4 polypeptide chains Two of these are H chains having a molecular weight of 50 000 to 60 000 and 2 are L-chains with a molecu

lar weight of 20 000 to 25 000 The heavy chains are held together by 3 S-S bridges and the light chains are linked each to 1 of the 2 heavy chains through 1 disulfide bond Thus according to Porter there exists a total of 5 interchain disulfide bonds per molecule However Palmer and Nisonoff (1964) have found only 1 S-S bridge between the 2 heavy chains and the total number of interchain disulfide bonds may be only 3

Papain is visualized to act on the heavy chains only In terms of the model piece III and F fragment correspond to the larger portion of the 2 H-chains pieces I II and S fragment correspond to the rest of the molecule consisting of the smaller portions of the split H chains plus L-chains

Of the 2 types of polypeptide chains L chains appear to have the greater structural significance Both molecular individuality as well as features shared by all γ globulins are expressed through them As indicated by starch gel electrophoresis of reduced antibodies and myeloma proteins individual species of 7S molecules differ primarily in their set of L-chains On the other hand these L-chains also carry the antigenic determinants that are characteristic for the entire family of γ globulins (Fahey 1963) Thus these polypeptide chains vary greatly among γ globulin molecules but must also contain regions that are constant in composition and identical for all γ globulin molecules

However the matter is even more complex There are 2 groups of light chains which are antigenically unrelated (Mannik and Kunkel 1963 Fahey 1963) In 7S γ globulin approximately 60 per cent of the molecules are endowed with L-chains of group I, and 30 per cent with those of group II An antiserum prepared against group I L chains will not react at all with group II molecules, and vice versa These types of L chain molecules are also found in 19S γ globulins β_A globulins and their pathologic counterparts (Mannik and Kunkel, 1962), as well as in γ_L globulin (Stevenson 1962) and Bence-Jones proteins In fact the 2 groups were originally discovered by Korngold and Lipari (1956) in Bence Jones proteins which consist entirely of light chains

In summary work on the chemical and the antigenic structure of γ globulin has led to the development of the following tentative concept The molecules of 7S and 19S γ

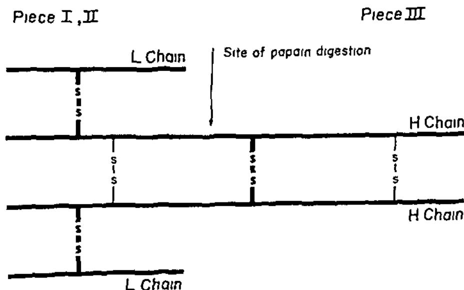

Fig 1 Structure of rabbit 7Sγ globulin as originally proposed by Porter (1962) who visualized three S S bonds linking the two H-chains and as modified by Palmer and Nisonoff (1964) who demonstrated that there is only one S S bond between the H-chains (In Porter s terminology H-chain = A-chain L-chain = B-chain)

globulin are composed of light and of heavy polypeptide chains The chains are interlocked by disulfide bonds γ_L Globulin (and Bence Jones proteins) consist of light chains only The heavy chains are specific for each class of γ globulin ie for 7S 19S γ globulin and for β_{2A} Within a given class there is little variation in heavy chain properties By contrast light chains exhibit no class specificity L-chains with the same general features occur in all 4 classes of γ globulin However they do possess group specificity giving rise to 2 categories of L-chains Each molecule of the γ globulin family belongs to either one or the other group depending on its L-chain make up In addition to these general structural features L-chains possess properties which confer individuality on a single species of γ globulin molecules thus giving rise to great molecular heterogeneity within the various classes

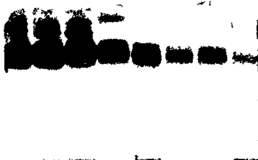

FIG 2 Starch gel patterns of reduced and alkylated guinea pig antibodies of different specificities (Edelman *et al* 1961) Direction of migration is toward the top The more slowly migrating bands represent H chains the faster ones L chains The first pattern on the left was obtained from whole guinea pig γ globulin The experiment demonstrates the variation in L chains between antibodies of different specificities

THE PROBLEM OF THE ANTIBODY COMBINING SITE

Theoretically specific antibody activity may be a function either of L-chains or of H-chains or of an interaction between both Since the S fragment of papain digested antibody behaves as univalent antibody it is evident that the larger portion of H-chains is dispensable for antibody activity and not involved in the active site What about the L-chains which are contained in S fragments? When purified antibodies against haptens are dissociated and examined by starch gel electrophoresis in urea discrete electrophoretic patterns are obtained (Fig 2) Antibodies of different specificities give rise to patterns which differ in the number and the distribution of the bands that represent L-chains However highly cross reactive antibodies yield patterns that resemble each other closely (Edelman *et al* 1961) It appears that antibodies of different specificities consist of different types of L-chains and that L-chains might therefore carry antibody combining activity However isolated L-chains proved to be completely inactive

Unlike L-chains purified H-chains from certain antibodies were found to be active in terms of specific inhibition of precipitation and in terms of co precipitation Recovery of specific activity was incomplete and varied with the degree of reduction (Fleischman *et al* 1963) Porter concludes that the combining region is located on H-chains and that the variability of L-chains is unrelated to antibody activity

However other recent reports indicate that L-chains although inactive *per se* bear an intimate relationship to the combining region Labeling of the combining site by different methods followed by dissociation of the antibody disclosed the presence of label in H and in L-chains (Metzger *et al* 1964 Roholt *et al* 1963) These observations suggest participation of L-chains in the formation of the active site although the extent of this participation and its significance for antibody activity remains unknown

Also unknown is whether the specificity of the combining region is determined by amino acid composition and sequence or by folding According to a hypothesis put forth

by Karush (1960), specificity is acquired by variable pairing of sulfhydryl groups and subsequent stabilization of conformation by disulfide bonds In this way a small number of disulfide bonds could afford the formation of a large number of different folding pat terns According to Buckley Whitney and Tanford (1963) this possibility appears to be eliminated by the available chemical data (Fleischman *et al* 1963) The number of distinguishable patterns which can be formed within the restrictions of the known ar rangement of intrachain S S bonds in pieces I and II is exceedingly small These authors conclude that antibody specificity is gen erated primarily by differences in amino acid sequence in some portion of the antibody molecule

COMPLEMENT

The term complement refers to a highly complex system of blood serum factors which possesses the potential capacity to cause ir reversible damage to cell membranes It con sists of at least 9 or 10 components the exact number being unknown It is activated by interaction with antigen antibody com plexes or γ globulin aggregates Activation is followed by a chain reaction which in volves all the components in characteristic sequence and results in loss of over all com plement activity By virtue of its combining power with γ globulin complement is capa ble of precipitating soluble antigen antibody complexes and of reacting with cell mem branes *For its cytotoxic action specific* antibody to cell membrane antigens is re quired in most instances The chemical mode of the complement reaction and the mecha nism by which complement interferes with normal membrane function are unknown

The Complement Reaction

The Components In the course of the discussion of antibodies it was possible to proceed from a mere description of serologic phenomena to an analysis of the underly ing molecular properties of antibody protein i e γ globulin A similarly illuminating ad vancement of our understanding of comple ment has not yet been achieved For most of the individual activities which together form the cytotoxic capacity of serum the chemi cal correlative is not known In the few in stances where it has been identified recently many of the physicochemical and chemical details have not been worked out Further with one exception none of these activities is defined in familiar biochemical terms They remain for the time being enigmatic serologic activities defined only by their role in the cytotoxic activity of fresh blood serum A comparison of the few isolated and puri fied complement components with each other and with γ globulin shows that complement components bear no antigenic resemblance to γ globulin and unlike different antibodies no resemblance to each other They appear to possess as different molecular properties as they have different functions in the com plement reaction

Originally complement activity was esti *mated by bacteriolysis* When immune hemolysis was discovered antibody-coated erythrocytes became the universally employed indicator system In most laboratories sheep erythrocytes are used and are sensitized with nonagglutinating quantities of antibody to sheep erythrocytes produced in rabbits The widespread use of erythrocytes as indicator cells has created the impression that comple *ment is primarily* hemolytic The fact is that a large variety of cells of mammalian origin as well as from lower animals and certain microorganisms are susceptible to the action of complement The advantage of using erythrocytes is that part of their intracellular protein is intensely colored and can b *readily quantitated spectrophotometrically* after liberation from the cells Therefore the amount of extracellular hemoglobulin is used commonly as a convenient measure for the number of red cells lysed by complement

That complement is not a single substance can be demonstrated easily by the separation of serum into euglobulins and pseudoglob ulins which is accomplished by dialysis of serum against buffer of low ionic strength Neither the euglobulins nor the pseudoglob ulins *per se* are capable of lysing antibody coated red cells However recombination of the 2 fractions results in reconstitution of the hemolytic activity of the original serum Treatment of serum with small amounts of ammonia or hydrazine as well as heating at

56 C for a short period of time also results in hemolytically inactive complement That the hydrazine sensitive material is not identical with the heat labile substance but that both are independent parts of the com plement system is shown by recovery of activity after pooling of the 2 differently treated sera In this and in similar fashion early students of complement succeeded in demonstrating that complement consists of at least 4 components with widely diverging properties These components were num bered and referred to as C'1 C 2 C'3 and C'4 C 1 and C 2 were found to be thermo labile and C 3 and C 4 thermostable com ponents C 1 and most of C'3 were charac terized as euglobulins C 2 and C 4 as pseudoglobulins C'3 could be preferentially inactivated by incubation of serum with zymosan which is an insoluble yeast poly saccharide and C 4 was destroyed by treat ment with ammonia or with hydrazine Analysis of the sequence of action of these 4 components in immune hemolysis estab lished that C 1 initiates the reaction and that this component is followed by the 4th the 2nd and finally the 3rd component

Only recently have the new and powerful protein separation methods been employed for the separation of complement activities After adsorption of serum to a DEAE cellu lose column the various complement compo nents are eluted in a characteristic sequence on variation of ionic strength or pH Applica tion of more complex chromatographic procedures has afforded the preparation of serum fractions which contain only one component Such preparations are referred to as functionally pure complement com ponents and have been used to great ad vantage in kinetic studies of the complement reaction (Mayer 1961a) It is important to realize at the outset that for the time being complement components are defined by their activities only because in most instances other parameters are unknown Therefore when a preparation of a component is con sidered to be functionally pure this does not imply and must not be confused with purity as defined by the criteria of protein chem istry In fact functionally pure components can be highly heterogeneous mixtures of proteins of which the active component con stitutes only a very small part

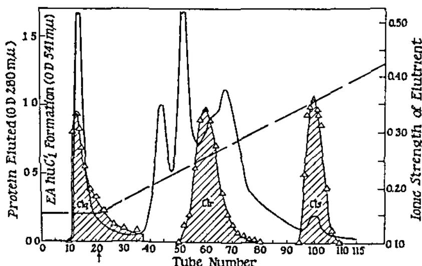

Fig 3 Separation of the classic first component of human complement into three subcomponents by DEAE chromatography (Lepow *et al* 1963) All three factors are required for generation of the activity of the classic first component It is an example of the molecular complexity of components previously believed to be monomolecular

In chromatograms of human or of guinea pig serum C 2 and C 4 activities can be de tected readily and are found in fractions which are definitely separable from each other (Rapp *et al* 1959 Becker 1960) However attempts to detect C'1 and C'3 activities have encountered considerable initial difficulty and have led subsequently to the realization that both C'1 and C'3 are complex each having a number of different activities C 1 of hu man serum is separated on chromatography into 3 subcomponents C'1q C'1r and C'1s (Lepow *et al* 1963) Recovery of whole C 1 activity is achieved only by recombina tion of the chromatographic fractions con taining the 3 subcomponents (Fig 3) Simi larly C 3 of guinea pig serum consists of 4 separate factors called C'3a, C'3b C 3c and C 3d (Linscott and Nishioka 1963) The new nomenclature of complement proposes to call these subcomponents of the classic 3rd component C'3 C'5 C'6 and C 7 accord ing to their sequence of action Provision has to be made for the discovery of additional factors essential for complement activity Indeed evidence has been obtained suggest ing the existence of at least one more com ponent which contributes to the activity of the classic 3rd component Details will be discussed below

The Reaction Steps Complement reactive sites on the cell surface are generated by the attachment of antibody molecules to mem brane antigens Complement binding ap parently requires that at least 2 antibody molecules must be brought together and held in close proximity to each other It is postulated that a site reactive with comple ment is formed either by 2 molecules of antibody of the 19S variety or by 4 of the 7S class (Weinrach and Talmage 1958) It follows that the degree of complement fixation should be dependent also on the distribution of antigenic sites on the cell surface If these are spaced so that antibody molecules will not attain the necessary degree of proximity interaction with complement would not be expected to occur The inability of Rh antibodies to fix complement has been explained in this fashion As further support for the above hypothesis the observation can be cited that the number of reactive sites on the surface of a sensitized cell is con siderably smaller than the total number of antibody molecules that have combined with it (Mayer, 1961a) To some extent anti body molecules are able to transfer from site to site and from cell to cell thus increasing the probability of formation of reactive sites and enhancing their hemolytic efficiency

The combining region for complement was originally attributed to fragment III of the antibody molecule (Taranta and Franklin 1961, Amiraian and Leikhim, 1961) After pepsin treatment which eliminates this part of the molecule complement fixation power is indeed strikingly reduced but is not com pletely abolished An appreciable proportion of the original fixation capacity is retained by the resulting 5S antibody derivative (Schur and Becker 1963) There is probably more than one region in the γ globulin molecule which is involved in interaction with comple ment The existence of at least 2 receptor sites has to be postulated one for the C'1 complex the other for C 4 since removal of C'1 from immune aggregates containing complement does not affect binding of C'4 Although the groups on γ globulin which are responsible for complement binding are unknown binding is dependent on an intact internal structure Reduction of disulfide bonds followed by alkylation a treatment which does not affect the molecular weight of 7S antibodies or their capacity to combine with antigen renders antibody molecules in capable of interacting with complement (Wiedermann *et al* 1963)

The first step of the complement reaction involves the components C'1q C 1r and C 1s and leads to the generation of esterase activ ity Upon uptake of the 3 components by re active sites the proesterase C 1s is activated presumably by the action of C'1q and C'1r (Lepow *et al* 1963) The product of this reaction EAC 1a is a cell (E) or a cellular site which contains antibody (A) and active first component (C 1a) and is ready to react with the next component Uptake of the whole C 1 complex requires participation of calcium ions although C'1q which will be discussed as 11S component has the ability to combine with γ globulin in the absence of bivalent cations This latter fact as well as moderate success in preparing the EAC 1q intermediate complex (Muller Eberhard

1961) has suggested a sequence of action which begins with C 1q and ends with C 1s Activated C'1 is able to transfer from site to site and from cell to cell as is typical of an enzyme it can react with many molecules of substrate (Borsos and Mayer 1962) When calcium is withdrawn from the reaction mixture the reaction between sensitized cells and the first component is reversed (Becker 1960) Under these conditions the fluid phase contains C'1 esterase as well as hemolytically active C 1 Although it is an enzyme, C 1 esterase is not involved in the actual process of cell lysis Its natural substrate is not the cell membrane but apparently 2 of the other complement components namely C 4 and C'2 Recent studies by Naff Pensky and Lepow (1964) indicate that the 3 subcomponents of C'1 occur in serum in the form of a macromolecular complex which is held together by Ca^{++} and has a sedimentation rate of 18S

The next event in the complement reaction is uptake by EAC 1a cells of C 4 activity a *step which depends entirely on the action of* C 1 esterase as evidenced by the failure of uptake on blocking of the esterase by DFP (diisopropyl fluorophosphate) Once C 4 activity is attached to the cell it is firmly retained even if subsequently C 1 is removed by treatment with EDTA (Becker 1960) Until recently it was not known whether uptake of C 4 activity corresponded to an actual attachment of the C'4 molecule or to an interaction with resulting change in membrane conditions and simultaneous destruction of C'4 activity in the fluid phase It has now been established that formation of EAC 1a 4 is dependent on physical uptake of the protein in which C'4 activity has been found to reside (Muller Eberhard and Biro 1963) This protein is called β_{1E} globulin and will be described below To combine with EAC 1a cells it must react with a receptor site located either on the antibody molecules or on the cell membrane since C 1 is excluded as a possible receptor While there is evidence for fixation of β_{1E} globulin to antibody in complement treated immune precipitates experiments to be alluded to later indicate that in cytolytic reactions β_{1E} globulin combines directly with the cell membrane

During the subsequent step C'2 reacts with EAC 1a 4 cells to produce intermediate complexes containing the activated form of the second component of complement C'2a This step requires magnesium ions In the somewhat awkward but systematic language adhered to by students of complement this product is symbolized by the expression EAC 1a 4 2a Two phases of this reaction can be distinguished during the first C 2 becomes loosely attached to EAC 1a 4 and during the second phase the activated first component acts on C 2 probably by cleaving the molecule and transferring an active group C 2a to a receptor on C 4 An inactive fragment C 2i is released into the fluid phase and can be demonstrated there by immunologic means (Mayer 1963) Activation which is highly dependent on temperature can be inhibited by agents which block or competitively inhibit C 1 esterase One of the peculiarities of C'2a is its marked lability which is particularly conspicuous at an elevated temperature and results in reversion of *the intermediate complex* EAC *1a 4 2a to the* EAC'1a 4 state (Mayer 1961a) The cause of the decay has not been elucidated It is prevented or perhaps it becomes undetectable and immaterial when the next 3 components of the complement system have completed their reaction with the cell Evidence is accumulating suggesting that C 2a constitutes an enzyme or at least part of an enzyme which acts on C 3

Conversion of an EAC 1a 4 2a cell to a state in which it will undergo spontaneous lysis is known to require at least 4 factors of guinea pig serum (Linscott and Nishioka 1963) Two of these are thought to be necessary to render an EAC'1a 4 2a cell unsusceptible to the effects of time and temperature i e to preserve its reactivity with the last 2 components of the system Although such an accumulation of factors may seem to be elaborate enough to achieve and to secure a simple biologic effect such as immune cytolysis the latest evidence indicates that actually 3 separate factors are required for the conversion of EAC 1a 4 2a to a stable intermediate thus at least 5 factors are necessary for the conversion of the same complex to an irreversibly damaged cell that finally will undergo lysis

The component which is able to react directly with EAC'1a,4 2a cells is defined as C'3 and has been identified with a protein in human serum designated β_{1C} globulin In the course of their interaction with cells containing C'2a a certain proportion of C'3 molecules is taken up and firmly retained by cellular sites while the majority of the molecules are released into the fluid phase in physicochemically altered and hemolytically inactive form Both uptake of C 3 and conversion to C 3i are highly temperature dependent processes they are independent of bivalent cations and are not catalyzed by C'1 esterase

Following C 3 two factors here referred to as C 5 and C'6, are the next ones to act Only if both of these components react with EAC'1a 4 2a 3 will an intermediate complex be formed which no longer displays the decay phenomenon so characteristic for its 3 immediate precursors (Nilsson and Muller Eberhard 1964 Nelson personal communication Wellensiek and Klein 1965) The stable complex may be represented by the expression EAC 1a 4 2a 3 5 6 It is characteristic for C'5 and C'6 that they require for their action the presence on the cell of both C 2a and C 3 If C 2a has decayed cells now in the state EAC'1a 4 3 can be restored to EAC'1a 4 2a 3 by addition of C 2 (Linscott and Nishioka 1963) C'5 of human serum has been identified with a protein which, on the basis of its immunoelectrophoretic behavior has been named β_{1F} globulin (Nilsson and Muller Eberhard 1964)

The final 2 steps lead to the critical changes in membrane integrity which initiate cell lysis After action of C 7 the cells exhibit increased fragility and this has been interpreted to indicate partial disintegration of cell membrane structure without breakdown of membrane function The fatal event is caused by C'8, after it has acted on the cells lysis ensues Heat lability of C 7 and C 8 and temperature dependence of the final reaction suggests that these 2 components may be enzymatic in nature (Linscott and Nishioka 1963) Since questions concerning nomenclature have not been settled definitively it should be pointed out that the terms C'3 5 6,7 8 used by the author correspond to C'3c b e a d of Nelson s terminology

The entire sequence of events is illustrated diagrammatically in Figure 4 Although there is reason to believe that an organism endowed with this highly complex cytotoxic mechanism has a selective advantage over one that lacks it one cannot help wonder why it is so unusually complex To our mind the biologic role of complement is revealed in its capacity to impair cell membranes Experimentally destruction of cell membranes in vitro and in vivo is accomplished readily by enzymes such as lecithinase and, indeed enzymatic activity is implicated in the final steps of complement action Why then has nature evolved and maintained this elaborate system when the task could be achieved essentially by a single enzyme? Evidently to be compatible with life cytotoxic activity must not occur in a

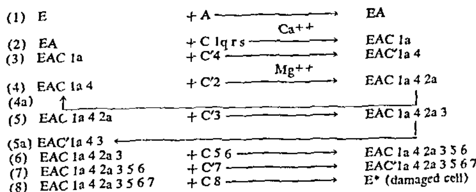

Fig 4 Complement reaction sequence

form which would act indiscriminantly Safety devices are required which impose rigid restrictions on its action and direct it to selected targets The components which precede the last 2 in the complement reaction may well represent such a device On the other hand one has to be mindful of the possibility that earlier steps of the complement reaction may have their own biologic significance which may be entirely unrelated to membrane damage As will be discussed below complement promotes phagocytosis for this to occur the reaction does not have to go to completion Similarly other as yet unidentified biologic functions may be associated with limited parts of the complement reaction or with individual components

Chemical Aspects

C'1 Esterase The discovery of the enzymatic nature of C 1 constitutes perhaps the most significant recent contribution in the complement field With this observation complement has come within reach of biochemical definition

The initial observation was made by Levine (1955) who found that diisopropyl fluorophosphate (DFP) a powerful inactivator of esterases inhibits immune hemolysis by guinea pig complement He also found that this effect is due to an action of DFP on EAC'1a 4 cells Subsequently Becker showed the affected component to be C 1a From his work (Becker 1956 1960) and that of Lepow (Lepow *et al* 1956 Ratnoff and Lepow 1957 Lepow *et al* 1963) the following concept evolved A portion of the first component C'1s represents an inactive proenzyme which cannot be inhibited by DFP Upon *interaction with C 1q and C 1r* as it occurs during immune hemolysis the proenzyme is activated and esterase activity ensues Unlike its precursor the activated enzyme is readily blocked by DFP as evidenced by disappearance of esterase activity and of C'1a hemolytic activity

The enzymatic activity of C'1a can be demonstrated with the aid of certain synthetic amino acid esters which are hydrolyzed by C'1a at the ester linkage For human C 1 esterase the most susceptible compound is N acetyl L tryosine ethyl ester p toluene sulfonyl L arginine methyl ester and benzoyl L arginine methyl ester also display a high degree of susceptibility whereas many other compounds of similar structure do not

Although no proteolytic activity has been demonstrated for C'1 esterase the enzyme is capable of destroying C 2 and C'4 activity in serum This may seem to be in striking contrast with its presumed function the catalysis of the union of C'4 and C 2 with antibody coated cells However if it is assumed that C 1 esterase acts identically in both cases for instance by splitting a bond which thereafter can react either with a cellular receptor site or with water then the discrepancy is resolved Whether a molecule is activated or inactivated by C 1 esterase may thus depend merely on the immediate availability or the lack of cellular receptor sites Much is in favor of such a hypothesis

For activation and uptake of C'1 calcium ions are important The role of calcium during activation is strictly specific (Mayer 1961) whereas a number of bivalent cations can substitute for calcium in establishing and maintaining the bond between C 1a and EA (Wirtz and Becker 1961) It is possible that calcium functions as a ligand linking 2 negatively charged molecules

More than 2 400 fold purification of C'1 esterase has been achieved by chromatographic technics (Haines and Lepow 1963) However these highly purified preparations are still not quite homogeneous in the ultracentrifuge and on immunochemical analysis The enzyme migrates as α globulin on paper electrophoresis and has an s rate of 4S

11S Component. When human serum is adsorbed with soluble aggregates of γ globulin in the presence of EDTA hemolytic complement activity is lost When this observation was first made it was most startling and at variance with the well established concept that complement cannot interact with immune aggregates in the absence of bivalent cations In confirmation of this widely held view it was found that none of the classic components was removed by this treatment. Therefore it was concluded that a factor had been eliminated from serum which although not a classic component is nevertheless essential for hemolytic complement activity and is capable of combining directly

with γ globulin even in the absence of cal cium ions This postulated factor was isolated from γ globulin aggregates which had been exposed to EDTA containing serum (Muller Eberhard and Kunkel, 1961)

Since the sedimentation coefficient of this new complement component is 11 1S it was tentatively called the 11S component Its electrophoretic behavior resembles that of a slow γ globulin it must be one of the most basic proteins of human serum Although it migrates in the electric field like a γ glob-ulin it bears no immunochemical relationship to γ globulin

When purified 11S component is added to a serum preparation previously depleted of this protein and thus rendered hemo-lytically inactive activity is fully restored The quantity of 11S component required for full restoration of activity corresponds to approximately 0 05 per cent of the total serum protein present in the reaction mix ture Interaction of the component with soluble immune or γ globulin aggregates results in their precipitation suggesting at least 2 combining sites on a molecule of 11S component Both hemolytic and precipitating activity are rapidly destroyed on heating of the protein to 56° C The bond between 11S component and antibody coated cells or soluble γ globulin aggregates appears to be weak It is much strengthened by the par ticipation of C 1r and C′1s

Lepow recently has shown that the 11S component which he calls C′1q together with C 1r is required for activation of C′1 esterase Thus present evidence suggests that the 11S component assumes the important function of initiating the complement reaction by combining with γ globulin molecules and by participating in the activation of C 1 ester ase An analogous activity has been described for rabbit and for guinea pig serum (Bar baro 1963)

β_{1E} Globulin This is the 4th component of human complement and the 1st of the classic components which has been isolated and characterized Isolation was accomplished by a combination of preparative electro phoresis and chromatography (Muller Eber hard and Biro 1963) The final product exhibited a high degree of physicochemical homogeneity and could be defined with the aid of antisera as a single immunochemical entity of human serum The protein was designated β_{1E} globulin It has a sedimenta tion coefficient of 10S which is independent of concentration It contains a carbohydrate moiety On treatment with dilute hydrazine which is known to inactivate C′4 the protein undergoes some distinct physicochemical changes

Before concluding that an activity resides in a given protein, it is necessary to demon strate their inseparability by a variety of separation procedures In addition whenever possible more specific criteria should be employed In the case of β_{1E} globulin such criteria are given by the known behavior of C′4 activity In complete analogy to C′4 activity β_{1E} globulin combines only with cells containing the active first component of com plement and not with sensitized cells or with DFP inhibited EAC 1a Further treatment with hydrazine renders β_{1E} globulin incap able of combining with EAC 1a cells but when EAC′1a 4 cells, which contain β_{1E} are treated with hydrazine β_{1E} remains cell bound as does C 4 activity The presence of β_{1E} globulin on the cell surface can be demonstrated either directly by using radio actively labeled β_{1E} or indirectly by aggluti nation of the cells with an antiserum to this component It thus appears that β_{1E} globulin represents human C′4 and that the conver sion of EAC 1a to EAC′1a 4 cells corre sponds to attachment of β_{1E} to the cells

β_{1C} Globulin Only after its isolation from human serum was this protein recognized as an essential part of the hemolytic comple ment system (Muller-Eberhard *et al* 1960) It is defined as C′3 because it interacts directly with cells containing C′2a (EAC 1a 4 2a) The reaction does not proceed at 0 C The protein migrates in the electric field as a slow β_1 globulin it has a sedimen tation coefficient of 9 5S is endowed with a carbohydrate moiety and is characterized by a pronounced lability On treatment with dilute hydrazine or ammonia or on aging it undergoes distinct physicochemical changes The altered protein has a greater electro phoretic mobility and a lower sedimentation rate (7S) it is designated β_{1A} globulin In this form the protein is hemolytically inactive

TABLE 2 PROPERTIES OF ISOLATED COMPLEMENT COMPONENTS

	11S COMPONENT	β_{1E} GLOBULIN	β_{1C}-GLOBULIN	β_{1F} GLOBULIN
20 w	11 1S	10 0S	9 5S	9 4S
Electrophoretic mobility	γ	β_1-α_2	β_2 β_1	β_1-α_2
Serum concentration (µg /ml)	20 30	30 50	300-400	30 50
Activity	C'1q	C'4	C'3	C 5
Receptor	EA	EAC'1a	EAC'1a 4 2a	EAC'1a 4 2a 3
Temperature requirement	0	0	+	
Inactivated by	heat	N_2H	N H	heat

The conversion from the active β_{1C} to the inactive β_{1A} form can be followed best by immunoelectrophoretic analysis of whole serum or of the isolated protein It is so conspicuous that this phenomenon originally led to the recognition of the protein as a potential complement component

During immune hemolysis when C 3 activity is consumed β_{1C} globulin is affected in seemingly two ways it is changed and it is in part attached to the cells Approximately 80 to 90 per cent of the protein is found after the reaction in the fluid phase It is present in an electrophoretically faster form closely resembling β_{1A} globulin but differing in that its sedimentation rate is practically unchanged To distinguish this reaction product from β_{1A} globulin the product of aging the term β_{1G} globulin is tentatively proposed Approximately 10 to 20 per cent of the original β_{1C} molecules are found to be in firm combination with the cell membranes Whether these molecules are in the β_{1C} or in the β_{1G} state or represent still another form is not known with certainty Some observations suggest that the protein occurs on the cell surface in more than one discrete form and that the form which is reactive with C 5 is β_{1G}

The chemical events underlying the conversion of β_{1C} globulin during the complement reaction have not yet been elucidated However since the phenomenon is temperature dependent and highly reproducible it may be postulated that it is mediated by an enzyme associated with the complement system When cells in the state EAC 1a 4 2a are reacted at 37 C with highly purified human β_{1C} globulin (free of detectable quantities of C'5 and C'6) conversion proceeds rapidly Since DFP inhibits neither uptake nor conversion and since cells previously decayed to the EAC'1a 4 state are completely inert to β_{1C} globulin it must be concluded that C'2a is responsible for uptake and conversion of β_{1C} globulin (Muller Eberhard *et al* 1964) The possible enzymatic nature of C'2a deserves serious consideration and exploration

β_{1F} Globulin This protein has been recognized only recently as a new entity of human serum and as the carrier of C'5 activity (Nilsson and Muller Eberhard 1964) Detection was faciliated by an antibody occurring in some antisera to β_{1C} globulin The original preparations of β_{1C} globulin were contaminated with small amounts of β_{1F} globulin Electrophoretically the protein behaves like a fast β globulin its sedimentation coefficient is 9 4S Its activity is exceedingly thermolabile

Table 2 summarizes a few characteristic features of the components isolated so far In spite of certain physicochemical similarities these proteins are completely unrelated to each other by immunochemical criteria They also are unrelated to γ globulin

OTHER HUMORAL FACTORS

In addition to antibody and complement some other factors may play a role in humoral defense mechanisms

LYSOZYME

This is an enzyme which is capable of lysing certain bacteria by attacking cell wall mucopeptides It is widely distributed in nature and occurs in the body fluids including serum and plasma of man and animals

FIG 5 Immunoelectrophoretic demonstration of two complement components in human serum The single precipitin line above represents B_{1C} globulin (C 3) it was obtained by filling specific anti B_{1C} antiserum into the longitudinal well at the top The line at the bottom represents B_{1E} (C 4) it was developed using a specific anti B_{1E} antiserum The trough in the middle was filled with antiserum to whole human serum

The richest source for lysozyme is egg white

Lysozyme is a basic protein with an iso electric point at pH 10 11 Its sedimenta tion coefficient ^{s} 20 w is 1 9S the molec ular weight 14 400 (Sophianopoulos *et al* 1962) It is stable at acid pH even when heated but unstable in alkaline pH The primary structure of egg white lysozyme has been worked out by Jolles *et al* (1963) who also showed that there is 1 disulfide bridge in the molecule

Lysozyme activity is commonly deter- mined by lysis of a gram positive coccus which was isolated by Fleming and named by him *Micrococcus lysodeikticus* Degra- dation of this microorganism by lysozyme results in the release of N acetylamino sugar compounds and N acetylamino sugar pep- tide complexes Lysozyme breaks the gly cosidic bond between carbon atom Number 1 of N acetylmuramic acid and carbon atom Number 4 of N acetylglucosamine (Salton and Ghuysen 1959) accordingly the en zyme is a β (1 4) N acetyl-hexosaminidase

BETA LYSIN

Beta lysin (Petterson, *1926*) also called the beta bactericidal system of serum is distinct from antibody and complement and also from lysozyme It is capable of killing a number of gram positive microorganisms by an unknown mechanism of action *Bacil lus subtilis* is commonly used to test for its presence in serum Beta lysin can be separated into two components which are both required for full bactericidal activity against *Bacillus subtilis* (Myrvik and Leake 1960) Com ponent I is precipitated at 16 per cent ethanol concentration and component II at 40 to 50 per cent Both components are heat stable and nondialysable neither is inactiv ated by ammonia The activity is potentiated by bicarbonate Heat stability distinguishes the system from complement components C'1 and C'2 resistance to treatment with am monia from components C'3 and C'4 Since addition of specific agglutinins to serum does not enhance the activity antibody is believed not to be involved Lysozyme from egg white cannot substitute for either component While quite a bit is known about what beta lysin is not little in fact is known about what it is Some light on its peculiar nature is shed by the finding that plasma even when pre pared without resort to anticoagulants mani fests no such bactericidal activity apparently the responsible factors are liberated from platelets during the clotting process (Hirsch 1960 Jago and Jacox 1961)

OPSONIN

Substances present in blood serum which act on bacteria to render them subject to phagocytosis are called opsonins They func tion by altering the surface conditions of ob jects to be ingested There appears to be a

number of substances in serum that can act as opsonin Antibody exerts a strong opsonizing effect in many instances and complement generally enhances this effect Phagocytosis of larger cells e g erythrocytes proceeds poorly or not at all in the absence of complement In certain instances still other serum factors come into play Hirsch has described a heat labile opsonin which is operative when specific antibody is lacking It is distinguished from antibody by the following properties it is not a γ globulin and it lacks specificity it is heat labile and is inactivated by dilute ammonia and hydrazine it reacts rapidly with bacteria at 38° C but not at 0 C (Hirsch and Strauss 1964) These properties are reminiscent of those of complement However the heat labile opsonin described by Hirsch is distinct from hemolytic complement in that it does not require calcium and magnesium for combination with bacteria The presence of this material on the surface of opsonized and washed bacteria can be demonstrated by the fluorescent antibody technic (Hirsch 1964) The chemical or immunochemical nature of the heat labile opsonin is unknown

Humoral Factors in Cellular Immune Mechanisms

Mention should be made of a group of humoral principles which are involved in cellular immune and defense mechanisms Hardly anything is known about their nature and practically nothing about their mode of action However the biologic role of these factors is so important that attention should be focused on them

A number of years ago Lawrence discovered that delayed sensitivity to bacterial and fungal antigens can be transferred from immune to nonimmune individuals by leukocyte extracts The active principle which originates from lymphoid cells was called transfer factor It is dialysable and has a molecular weight of less than 10 000 Its activity is resistant to treatment with DNAse and RNAse The factor is released on contact of sensitized lymphoid cells with the antigen The significance of transfer factor derives from its ability to endow recipients with delayed sensitivity *de novo* In other words this factor is capable of transferring immunologic information and of causing the recipient to possess the immunologic memory of the donor for prolonged periods (Lawrence 1960)

Recently Najarian and Feldman (1963) demonstrated the transfer of homograft immunity by a soluble substance which was obtained from disrupted tissue sensitized lymphoid cells The material possessed immunologic specificity and was not identical with transfer factor Thermostability solubility and chromatographic characteristics suggested to these authors that it might be γ globulin representing transplantation antibody

Another recent and most interesting development is the demonstration by Levey Trainin and Law (1963) of a humoral factor that diffuses from thymic tissue and appears to be responsible for the evolution of immunologically competent lymphoid tissue Mice thymectomized within 12 hours after birth develop the characteristic symptoms of neonatal thymectomy marked lymphopenia involution of lymphoid tissue and severe wasting disease Death occurs at 7 to 8 weeks of age In contrast these symptoms did not develop when a cell tight diffusion chamber containing isologous newborn thymus was implanted in 3 to 4 week-old thymectomized mice These animals did not show depletion of lymphocytes or involution of lymphoid tissue or any signs of wasting disease Independently Osoba and Miller (1963) demonstrated that a humoral factor of embryonic or neonatal thymus is able to restore the capacity to reject homografts in thymectomized mice

Elucidation of the nature of this group of humoral factors will contribute considerably to the advancement of our understanding of immune phenomena

EFFECT OF ANTIBODY AND COMPLEMENT ON CELL MEMBRANES

Effect of Antibody

Effective immune cytolysis requires both antibody and complement To evaluate critically the role of complement it is necessary to determine whether antibody alone might be capable of inducing some changes in cell

metabolism or morphology Easton, Goldberg and Green (1962) have studied this question extensively, utilizing Krebs s ascites tumor cells Viewing the cells with the electron microscope they found that ferritin labeled cytotoxic antibody was localized on the outer cell membrane None of the ferritin label was detected inside the cell, indicating that antibody cannot pass the membrane of intact cells Even over prolonged periods of time antibody had no effect on the cytoplasmic structures mitochondria and endoplasmic reticulum However it did induce folding of limited portions of the outer cell membrane particularly in those areas where the antibody concentration was especially dense These folded areas appeared to facilitate agglutination, since interdigitation of surface projections of adjacent cells was observed frequently The morphologic change induced by antibody was not accompanied by any functional lesion In fact the cells could be grown in normal fashion with cytotoxic antibody present These results support the concept that cytotoxic antibody alone has no adverse effect on cells and that its function in immune cytolysis is to mediate the action of complement Further evidence of the mediating role of specific antibody is provided by observations indicating that antibody can be replaced by so-called nonspecific sensitizers

Nonspecific Sensitizers

A number of substances which chemically have nothing in common with antibody have been shown to function as sensitizers in immune hemolysis The most thoroughly studied is polyethylene glycol Cowan (1954) demonstrated its ability to replace antibody in the conventional hemolytic system consisting of sheep red cells rabbit antibody and guinea pig complement For effective hemolysis the concentration of polyethylene glycol in the reaction mixture had to be approximately 6 per cent and the concentration of calcium 5 times the conventional value Under these conditions the reaction resembled in all phases the ordinary type of immune hemolysis which depends on antibody Since cells treated with polyethylene glycol do not remain sensitized during subsequent washing Cowan concluded that this substance functions as a sensitizer by forming a loose, reversible link between the cell surface on the one hand and complement on the other

An alternative mechanism of action is suggested by the finding that polyethylene glycol causes reversible aggregation of γ globulin in whole serum (Dalmasso and Muller Eberhard 1964) These aggregates are capable of interacting with complement Therefore, it appears probable that polyethylene glycol causes γ globulin in the reaction mixture to aggregate and then binds some of the aggregates loosely to the cells Complement reacting with aggregates which are in close proximity to the cell surface thus may affect the cell membrane directly Whether processes similar to these in vitro experiments can occur in vivo is unknown

The use of polyethylene glycol has aided the exploration of complement-cell membrane interaction substantially Cells first treated with polyethylene glycol and human serum lacking cytotoxic antibody and then thoroughly washed were found to be coated heavily with β_{1E}- and β_{1C} globulin As judged by negative agglutination reactions with specific antisera these cells did not contain any of the 3 γ-globulins 7S γ globulin 19S γ globulin, β_A globulin Therefore it appears that the continued presence of these 2 complement components on the cell surface is not dependent on a sensitizer antibody or γ globulin It must be postulated that both components are capable of establishing a direct link with membrane sites

Nature of Lesion Caused by Complement

Morphology of Lysis of Mammalian Cells Goldberg and Green (1959) have conducted electron microscopic studies on Krebs s ascites tumor cells treated with specific antibody plus complement Within 2 minutes at 37° C dramatic morphologic changes become observable The cells begin to swell and large areas of the cytoplasmic matrix are cleared of all particulate structures The small electron-dense particles which form the background density of normal cells disappear Mitochondria and the endoplasmic reticulum also swell and give rise to the formation of large cytoplasmic vesicles All

these changes occur in the absence of detectable defects in the integrity of the outer cell membrane However Borsos Dourmashkin and Humphrey (1964) using negative staining with potassium phosphotungstate were able to demonstrate holes in the membranes of a variety of cells which had been lysed by antibody and complement The holes had a diameter of 80 to 100 A

The Permeability Defect The morphologic changes are accompanied by a drastic redistribution of water small ions and macromolecules between the cytoplasm and the outer fluid Within 5 minutes after the onset of complement action 90 per cent of the intracellular potassium has left the cells and extracellular sodium has entered them At this time only 15 per cent of intracellular protein has escaped Later after 1 or 2 hours 50 per cent of intracellular protein 75 per cent of RNA and most of the amino acids and the nucleotides have leaked into the supporting medium (Green *et al* 1959)

A thorough study of the escape rate for small and for large molecules has enabled Green Barrow and Goldberg (1959) to describe the course of events of cytolysis in the following way the action of antibody and complement gives rise to functional holes of small size in the membrane which permit free exchange of potassium and sodium between the interior and the exterior of the cell Equilibration results in an increased intracellular osmotic pressure The reason for a rise in intracellular pressure is the high concentration of cytoplasmic macromolecules With rising osmotic pressure following the action of antibody and complement water enters the cells and they swell Concomitant stretching of the cell membrane causes the primary lesions now to permit passage of macromolecules Swelling of the cells and subsequent loss of macromolecules can be prevented by a high concentration of extracellular protein sufficient to balance the intracellular colloid osmotic pressure Sucrose does not prevent swelling it can pass through the initial lesions into the interior of the cells Thus immune cytolysis represents a form of colloid osmotic lysis The nature of the initial lesion is still obscure

Formation of Spheroplasts from Gram Negative Microorganisms In the case of bacterial cells the primary injury caused by antibody and complement appears to involve the cell wall not the membrane The plasma membrane of bacteria is not immediately accessible since it is located on the inside of the cell wall The firm structure of the wall serves to prevent the cells from bursting in hypotonic environments For bacteria most environments are hypotonic because of their own high intracellular osmotic pressure Theoretically complement might destroy bacteria either by damaging the cell wall thereby depriving the underlying membrane of the much needed mechanical support, or it might impair the functional integrity of the plasma membrane causing leakage of intracellular constituents through an unharmed cell wall The latter alternative would require that the intact cell wall be permeable to macromolecules of the size of complement components

Recently several groups of investigators have studied the primary events in bacteriolysis induced by antibody and complement They found that lysis of bacteria can be prevented by high concentrations of sucrose or lactose in the medium Under these conditions the organisms convert to protoplast like osmotically fragile forms which remain viable as long as osmotic protection is provided The phenomenon has been demonstrated for *Shigella dysenteria* (Michael and Braun 1959) *Salmonella typhosa* and *Escherichia coli* (Muschel *et al* 1959) and for *Vibrio cholerae* (Freeman *et al* 1963) Evidently the action of complement is directed against the cell wall not the plasma membrane There is some evidence that the cell wall is not completely removed by complement but is sufficiently altered as to allow the cell to assume a spherical shape

Penicillin in the presence of sucrose also causes the formation of spheroplasts from gram negative organisms However the mode of action of complement and of penicillin differs (Michael and Braun 1959) Penicillin is most effective on bacteria which are in the exponential phase of growth complement is effective on bacteria in the stationary phase Penicillin interferes with cell wall synthesis complement appears to act enzymatically on cell walls previously formed

The One Hit Theory The number of

lesions required for lysis of a cell by complement is undoubtedly a reflection on the nature of the injury inflicted For immune hemolysis, Mayer (1961b) has postulated a one-hit or single site reaction mechanism His theory proposes that the production of a single damaged site is sufficient for lysis This is difficult to comprehend in view of the limited size of the membrane defect caused by complement It would seem to be reasonable and biologically sound to assume that a cell can compensate for a single lesion which is so small as to allow only electrolytes to pass freely The one hit theory was developed by Mayer when he found that the absolute velocity and the extent of the hemolytic reaction are independent of the total number of cells in the reaction mixture The observation precluded the possibility of a multiple hit or cumulative damage mechanism However it does not necessarily exclude the possibility that more than one molecule of any one of the complement components may interact with a single cellular site What the theory requires is that a single molecule of at least one of the components involved in the hemolytic reaction suffices for the production of a damaged site i e for at least one of the reaction steps there should exist a direct proportionality between the amount *of the complement component reacting* and the number of sites produced According to Borsos Rapp and Mayer (1961) this condition is fulfilled for the reaction between EAC'1a 4 and C'2 and according to Hoffmann (1960) for the interaction of EA with C 1 and of EAC 1a with C 4 A satisfactory correlation was found to exist between the number of lesions predicted on the basis of the one hit theory and the lesions actually counted by electronmicroscopy (Borsos Dourmashkin and Humphrey 1964)

Mode of Action of Complement

Three Hypotheses The injury caused to cell membranes by complement may be due to mechanical stress or direct enzymatic attack or to a nonenzymatic cytolytic agent produced in the course of the complement reaction The first two hypotheses imply a direct and the last an indirect mode of action of complement on cell membranes

The hypothesis of indirect action through a cytolytic agent is old but has been revived recently and tested experimentally by Fischer and Haupt (1961) These authors found that when fresh serum is treated with antigen antibody precipitates, a cytolytic substance is produced The material was isolated and identified by paper chromatography as lysolecithin While a protein free filtrate of fresh guinea pig serum contained only 0 5 μg of lysolecithin per ml, 3 7 μg/ml were found after incubation of serum with immune complexes A similar increment in the lysolecithin content of serum was not observed when any one of the classic complement components was inactivated prior to treatment The authors conclude that lysolecithin represents the end product of the complement reaction and the substance to which complement owes its cytotoxic capacity

The lysolecithin hypothesis implies that one of the two terminal complement components is a lipoprotein capable of donating lecithin and the other an enzyme which is able to convert lecithin to lysolecithin However a serious difficulty arises from quantitative considerations According to Fischer and Haupt, $3\ 85 \times 10^{10}$ molecules of lysolecithin are necessary for lysis of a single human erythrocyte Accordingly only 10^5 erythrocytes should be lysed by the amount of lysolecithin liberated from 1 ml of serum whereas the total hemolytic capacity of this amount of serum is far greater Therefore, it was postulated that the efficiency of lysolecithin is much increased when it is liberated at a critical site on the cell surface On the basis of present experimental evidence the lysolecithin hypothesis can be neither refuted nor accepted

Mechanical stress appears to be the least likely cause of the effect of complement on membranes No doubt a considerable number of complement molecules accumulate at a single reactive site therefore the possibility of increasing mechanical stress is by no means excluded but it seems unlikely to be the primary cause of membrane injury A cell in the state EAC'1a 4 2a 3 5 6 probably has taken up all the complement macromolecules which are capable of permanent attachment since C'7 and C'8 which are not depleted in immune reactions (Linscott and Nishioka 1963), probably are not

bound Yet such a cell does not display any tendency to lyse

Marked thermolability of C7 and C8 (Linscott and Nishioka 1963) and lack of their depletion in immune reactions are consistent with the assumption of an enzymatic mode of complement action

The "Substrate" Plasma membranes are thought to be composed of a bimolecular leaflet of lipid covered on both surfaces with a layer of protein Such a concept is consistent with the structure of membranes as observed in high resolution electron micrographs (Stoeckenius 1962) Accordingly there are at least 2 possible substrates for complement lipid and protein

Observations on immune bacteriolysis suggest that complement acts on lipid or lipopolysaccharide complexes Gram positive bacteria are generally resistant to destruction by complement their cell wall is deficient in lipid Gram negative microorganisms may be killed and lysed by antibody and complement A large proportion of their cell wall consists of lipid complexes Moreover lysis of gram negative organisms by complement can be inhibited by certain phospholipid compounds (Ginsburg 1960) Therefore the assumption may be justified that gram negative organisms and mammalian cells are susceptible to complement because of the lipid moiety in their wall and membrane respectively

Further evidence for the lipid nature of the substrate of complement has come from work on immune inhibition of the electron transfer system (Davis *et al* 1963) Antibodies against rat mitochondria have *per se* very little effect on the activity of dihydro diphosphopyridine nucleotide (DPNH) oxidase However marked inhibition is observed on addition of complement to the system Since DPNH-oxidase consists of a complex chain of oxidation reduction components it is not immediately evident with which component complement is interfering The electron transfer chain includes cytochrome C which functions as an electron bridge between the 3rd and the 4th component in the chain (Green and Fleischer 1963) Apparently it is here that complement exerts its effect because the complement inhibited system can be reactivated by the addition of small amounts of cytochrome C

The components of the electron transfer system including cytochrome C have been shown to occur in the form of complexes with phospholipids (phosphatidylcholine phosphatidylethanolamine phosphatidylinositol and polyglycerol phosphatide) These compounds are of vital importance for the activity of the electron transfer system since activity is lost when they are extracted and is regained when they are replaced (Green and Fleischer 1963) In view of the importance of phospholipids to the system it may not be too surprising that phospholipase A is able to inactivate DPNH-oxidase As in the case of inhibition by complement the effect of phospholipase is overcome by exogenous cytochrome C Phospholipase presumably cleaves the phospholipid-cytochrome C complex (Ambe and Crane 1959) Since phospholipase is also capable of rapidly lysing mammalian cells it may be concluded that the action of complement resembles in certain respects that of phospholipase

HUMORAL MECHANISMS OF HOST DEFENSE

Neutralization of Viruses and Bacterial Toxins

The capacity of viruses to infect cells and to multiply is readily inactivated by specific antibody Virus is accessible to antibody only as long as it is outside cells Antibody is not virucidal i e it does not destroy virus particles Instead antibody interferes with the attachment of virus to potential host cells There are 2 phases of virus attachment the initial reversible binding and the subsequent formation of an irreversible bond between virus and cell surface Whereas antibody does not interfere with reversible attachment of virus it does block the reaction leading to irreversible attachment Since the latter is a prerequisite for penetration and invasion of the host cell a neutralized virus particle is rendered incapable of injecting its constituents into the cell

Not all antivirus antibodies possess the capacity to neutralize Antibody to bacteriophages for instance may be directed against either the head or the tail antigen Since a phage particle combines with a host cell through groups located at the tip of its tail

only antitail antibody is able to neutralize the phage The surface of the phage tail is visualized to contain a repeating pattern of antigenic structures which enables it to accommodate a large number of antibody molecules However neutralization of a phage particle is effected by only a very few antibody molecules in fact a single molecule may suffice This is inferred from kinetic studies which indicate that the rate limiting step is the reaction of 1 antibody molecule with 1 virus particle (Cann and Clark 1956) Various aspects of the problem of virus neutralization by antibody have been discussed by de St Groth (1962) and by Talmage and Cann (1961)

In addition to immune antibody normal mammalian sera of various sources have been reported to possess virus neutralizing activity Recently several groups of investigators (Cowan 1962 Muschel and Toussaint 1962) studied the inactivation of coliphages by normal sera These authors found that normally occurring specific antibody as well as complement participates in the reaction Unlike immune antibody normal serum antibody is *per se* not effective against viruses although it does combine with phage particles even in the absence of complement Neutralization occurs only when complement and bivalent cations are present The observed complement requirement suggested a mechanism of neutralization for normal serum which differs from that ascribed to immune antibody However the possibility of a virucidal action of complement could be excluded Inactivation by normal serum is completely reversed on treatment of neutralized phage with papain (Muschel and Toussaint 1962)

A number of animal viruses have also been shown to be inactivated by normal serum In certain cases serum substances other than antibody and complement have been held responsible for the effect These substances have been discussed by Ginsberg (1960)

Little is known about the mechanism of neutralization of bacterial toxins although there are indications that it is similar to the neutralization of viruses Many pathogenic species of gram positive bacteria produce exceedingly poisonous protein exotoxins (see Chap 7) Antitoxin appears to exercise its neutralizing effect by preventing the interaction between toxin molecules and susceptible sites in the tissues How many antitoxin molecules are needed for neutralization of one molecule of toxin has not been established unequivocally As in the case of viruses neutralization is reversible by dissociation of the toxin antitoxin complex

DESTRUCTION OF MICROORGANISMS

Many microorganisms including some pathogenic species, are killed by fresh serum It appears to be reasonable to postulate that these substances sometimes function in vivo as they do in vitro and that they constitute *important host defense factors*

Killing of gram positive microorganisms by serum is attributed to the action of beta lysin a bactericidal system which has been discussed above In brief, the system consists of two heat stable components (I and II) of unknown nature which bear no resemblance to antibody and complement Sera from healthy human beings contain relatively low levels of beta lysin activity due to a deficiency in component I In contrast acute phase sera are very active owing to a rapid rise in concentration of component I during the early stages of an infection (Myrvik and Leake 1960)

Gram positive organisms are also susceptible to the action of lysozyme This enzyme which occurs in human serum in a concentration of approximately 5 μg/ml attacks mucopeptide complexes in bacterial cell walls Some of the bacteria which are most easily lysed by lysozyme belong to the genera *Micrococcus Sarcina Staphylococcus* and *Bacillus* (Salton 1957) Thus at least part of the bactericidal activity of serum for gram positive microorganisms may be due to lysozyme

The destruction of gram negative bacteria is commonly ascribed to the action of complement and antibody Some of these organisms undergo overt lysis when treated with serum whereas others are killed without lysis If lysis occurs as in the case of *Sh dysenteria S typhosa E coli* and *V cholerae* it results from primary damage to the cell wall not to the plasma membrane Lysis is preceded by conversion of these

organisms to spheroplasts According to Muschel and Treffers (1956) destruction of one bacterial cell of *S typhosa* requires 700 to 860 molecules of antibody and 1 5 $\times 10^7$ molecules of complement the latter being estimated on the basis of complement nitrogen values and an assumed molecular weight of complement of 160 000

While lysozyme cannot lyse gram negative bacteria as long as their cell wall is intact it definitely can do so in the presence of EDTA or after certain pretreatments of the organisms (Salton 1957 Repaske 1958) The cell wall has been demonstrated to contain the mucopeptide substrate of lysozyme (Mandelstam 1961) however the molecular arrangement of the wall is such that the enzyme cannot gain access to it The mucopeptide complexes are probably covered by lipid or lipoproteins and they become accessible only after the organization of the lipid moiety has been impaired Since complement seems to affect the lipid moiety in cell walls treatment with complement should render gram negative cells susceptible to lysozyme Consequently lysozyme should enhance the bactericidal effect of antibody and complement although *per se* it is not bactericidal for gram negative bacteria Indeed enhancement of the bactericidal action of antibody and complement by lysozyme has been observed (Wardlaw 1962 Muschel 1963)

Promotion of Phagocytosis

Serum promotes phagocytosis by interacting with the particle to be ingested (Wright and Douglas 1904) and not by supporting the function of the phagocytic cell as Metchnikoff believed The action of serum on microbes and other objects results in an alteration of their surface properties thereby facilitating their attachment to phagocytes Factors responsible for phagocytosis promoting activity of serum are called opsonins A number of different opsonins have been distinguished and include antibody complement and heat labile factors of unknown nature Whether one or the other opsonin comes into play in a given situation depends largely on the nature of the surface constituents of the object to be ingested

In vitro Studies Microorganisms In relation to opsonin requirement for phagocytosis bacteria can be divided into 3 general classes some which require no serum for ingestion others which are engulfed when either heat labile opsonin or antibody is present and still others representing encapsulated strains which are ingested only in the presence of specific antibody (Hirsch and Strauss 1964) The first class is exemplified by group A streptococcus devoid of hyaluronic acid capsule and M protein the second by *Staphylococcus albus* and the third by *Klebsiella C* Obviously immune antibody exerts in most instances an adequate opsonic effect on microorganisms so that additional heat labile components are rarely needed However in the absence of specific antibody phagocytosis depends heavily on heat labile opsonins Therefore it is likely that these latter factors assume a special significance in vivo when immune antibodies to invading microorganisms have not yet reached effective serum concentrations

Heat labile opsonin shares its most characteristic feature thermolability with both natural antibody and complement However according to Hirsch and Strauss (1964) it is not identical with either These authors studied heat labile opsonin in rabbit serum and found that it differs from natural antibody in that it lacks specificity for bacterial antigens does not function at 0 C is not a γ globulin and is inactivated by dilute ammonia or hydrazine While hydrazine sensitivity and temperature dependence of the opsonic reaction would relate heat labile opsonin to hemolytic complement complete independence of the reaction of bivalent cations seems to preclude an identity However the possibility exists that the material is related to at least part of the complement system namely to one of the two hydrazine labile components Indeed there is evidence suggesting that β_{1C} globulin constitutes a factor of the heat labile opsonin system in human serum Regarding the mode of action of heat labile opsonin on bacteria information is scarce except for the important fact that it combines firmly with the bacterial cell surface (Hirsch 1964) Serum opsonins act by combining with constituents of the bacterial surface thereby neutralizing their

only antitail antibody is able to neutralize the phage The surface of the phage tail is visualized to contain a repeating pattern of antigenic structures which enables it to accommodate a large number of antibody molecules However neutralization of a phage particle is effected by only a very few antibody molecules in fact a single molecule may suffice This is inferred from kinetic studies which indicate that the rate limiting step is the reaction of 1 antibody molecule with 1 virus particle (Cann and Clark 1956) Various aspects of the problem of virus neutralization by antibody have been discussed by de St Groth (1962) and by Talmage and Cann (1961)

In addition to immune antibody normal mammalian sera of various sources have been reported to possess virus neutralizing activity Recently several groups of investigators (Cowan 1962 Muschel and Toussaint 1962) studied the inactivation of coliphages by normal sera These authors found that normally occurring specific antibody as well as complement participates in the reaction Unlike immune antibody normal serum antibody is *per se* not effective against viruses although it does combine with phage particles even in the absence of complement Neutralization occurs only when complement and bivalent cations are present The observed complement requirement suggested a mechanism of neutralization for normal serum which differs from that ascribed to immune antibody However the possibility of a virucidal action of complement could be excluded Inactivation by normal serum is completely reversed on treatment of neutralized phage with papain (Muschel and Toussaint 1962)

A number of animal viruses have also been shown to be inactivated by normal serum In certain cases serum substances other than antibody and complement have been held responsible for the effect These substances have been discussed by Ginsberg (1960)

Little is known about the mechanism of neutralization of bacterial toxins although there are indications that it is similar to the neutralization of viruses Many pathogenic species of gram positive bacteria produce exceedingly poisonous protein exotoxins (see Chap 7) Antitoxin appears to exercise its neutralizing effect by preventing the interaction between toxin molecules and susceptible sites in the tissues How many antitoxin molecules are needed for neutralization of one molecule of toxin has not been established unequivocally As in the case of viruses, neutralization is reversible by dissociation of the toxin antitoxin complex

Destruction of Microorganisms

Many microorganisms including some pathogenic species, are killed by fresh serum It appears to be reasonable to postulate that these substances sometimes function in vivo as they do in vitro and that they constitute important host defense factors

Killing of gram positive microorganisms by serum is attributed to the action of beta lysin a bactericidal system which has been discussed above In brief the system consists of two heat stable components (I and II) of unknown nature which bear no resemblance to antibody and complement Sera from healthy human beings contain relatively low levels of beta lysin activity due to a deficiency in component I In contrast, acute phase sera are very active owing to a rapid rise in concentration of component I during the early stages of an infection (Myrvik and Leake 1960)

Gram positive organisms are also susceptible to the action of lysozyme This enzyme which occurs in human serum in a concentration of approximately 5 μg/ml attacks mucopeptide complexes in bacterial cell walls Some of the bacteria which are most easily lysed by lysozyme belong to the genera *Micrococcus Sarcina Staphylococcus* and *Bacillus* (Salton 1957) Thus at least part of the bactericidal activity of serum for gram positive microorganisms may be due to lysozyme

The destruction of gram negative bacteria is commonly ascribed to the action of complement and antibody Some of these organisms undergo overt lysis when treated with serum whereas others are killed without lysis If lysis occurs as in the case of *Sh dysenteria S typhosa E coli* and *V cholerae* it results from primary damage to the cell wall not to the plasma membrane Lysis is preceded by conversion of these

rat erythrocytes is strikingly reduced (Spiegelberg *et al* 1963) The rate of clearance becomes normal even in these decomplemented mice if the bacteria or the red cells are treated with fresh mouse serum in vitro prior to injection If they are incubated with heat inactivated serum instead restoration of clearance is not observed Since opsonization of both rat erythrocytes and *E coli* with fresh mouse serum is completely prevented by EDTA it may be concluded that the opsonizing factor is related to hemolytic complement

NON-COMPLEMENT BINDING ANTIBODY The participation of complement in phagocytosis in vivo was corroborated further in studies employing antibody rendered incapable of binding complement Pepsin digestion of antibody produces a bivalent 5S antibody fragment which is still capable of precipitation and agglutination of antigen but has lost most of its ability to fix complement Erythrocytes coated with such digested antibody were eliminated from the blood of mice as slowly as untreated erythrocytes (Spiegelberg *et al* 1963) The antibody used had an s rate of 7S and on treatment with mercaptoethanol became nonhemolytic although its s rate and valency were unchanged Evidently it had lost the intramolecular organization which is a prerequisite for complement fixation However it had also lost its opsonic function (Miescher *et al* 1963) This is good evidence for an opsonin function of complement or parts thereof in vivo These studies were performed in mice the results are not necessarily representative for all other mammalian species In the human for instance certain erythrocytes coated with non-complement fixing antibody are cleared rapidly (Mollison 1962)

Immune Adherence Nelson (1963) has furnished evidence that phagocytosis of microorganisms in vitro and in vivo might be aided substantially by their adherence to erythrocytes Human and monkey red cells possess receptors on their surface allowing the attachment of particles which are coated with antibody and complement The nature of the cellular receptor site is unknown but the component of complement responsible for the adherence phenomenon has been determined and is according to Nelson identical with β_{1C} globulin Thus a complement treated erythrocyte which has reached the state EAC 1a 4 2a 3 will give rise to a positive immune adherence phenomenon on addition of primate cells This can be observed under the microscope or can be recognized macroscopically by overt agglutination Pertinent in this connection is the demonstration by Nelson that phagocytosis of bacteria in vitro is considerably enhanced in the presence of primate erythrocytes Apparently the phagocytic cell can get hold of a small particle more easily when it adheres to a large surface The erythrocytes are not ingested under these conditions

Immunoconglutinin. This is an autoantibody to fixed complement which is produced in man and animals in response to the invasion of the body by microorganisms (Coombs *et al* 1961) It appears to be a typical γ globulin with a sedimentation rate of 7S and 19S The specificity of immunoconglutinin is directed against chemical groups of complement which are hidden in the native molecules but are revealed during the interaction of complement with antigen antibody complexes Lachmann (1962) found that cells in the state EAC 1a 4 2a are not conglutinated i e agglutinated by immunoconglutinin However treatment of this intermediate complex with isolated β_{1C} globulin rendered it highly susceptible to conglutination Thus in all probability the antigenic determinants which are reactive with immunoconglutinin are derived from β_{1C} globulin That this protein undergoes characteristic physicochemical changes during the complement reaction has been discussed above

Coombs *et al* (1961) have accumulated evidence indicating that immunoconglutinin has an effect on resistance to bacterial infections In the mouse the conglutinin level can be raised readily by the injection of either live or killed bacteria Mice with immunoconglutinin in their circulation clear bacteria from the blood more rapidly than control mice furthermore bacterial counts of liver and spleen show enhanced intracellular killing

Attraction of Leukocytes by Serum Factors In concluding the discussion of phago

antiphagocytic effect, which otherwise would prevent attachment to phagocytes

In the case of some group A streptococci two distinct antiphagocytic surface materials can be distinguished M protein and hyaluronic acid To render these microbes susceptible to engulfment by phagocytes 2 different opsonins are required specific antibody to M protein and a heat labile factor The latter differs from the heat labile opsonin discussed above, since it occurs in human but not in rabbit serum The factor has been shown to counteract the antiphagocytic effect of the hyaluronic acid capsule (Hirsch and Church 1960) it does not seem to be a component of complement since serum can be depleted of it without affecting any of the classic complement components (Stollerman *et al*, 1963)

According to Jenkin (1963) serum opsonins may have important functions beyond the promotion of phagocytosis and also play a role in determining the fate of ingested bacteria In the absence of serum opsonins certain bacteria survived and multiplied intracellularly whereas they were killed in the phagocytes when previously exposed to serum

ERYTHROCYTES The opsonic requirements for the ingestion of red cells apparently differ from those of bacteria This might be expected in view of their rather different surface properties Antibody alone is not a sufficient opsonin for red cells a heat labile material is necessary in addition to antibody Nelson (1962) identified the heat labile material as part of the hemolytic complement system He established the requirements of the 1st the 2nd and the 4th component and of C 3c which is analogous to β_{1C}-globulin Thus the complement reaction need not go to completion for the production of an opsonic effect The critical condition appears to be the presence of β_{1C} globulin on the cell surface Antiserum to β_{1E} globulin and to β_{1C}-globulin have been shown to inhibit the ingestion of red cells (Gerling Petersen and Pondman 1962)

In Vivo Studies The nature of opsonic factors operative in vivo is difficult to determine, since the experimental conditions are not readily controlled In spite of intrinsic difficulties the problem has been tackled by several investigators, and interesting results have been obtained In vivo phagocytosis of gram positive and gram negative organisms and of colloidal particles like carbon is dependent on serum opsonins These opsonins are thought to be identical with antibody and complement and it is felt that there exists a reciprocal relationship between the quantities of the two substances required for effective opsonization

DEPLETION OF OPSONIN The critical role of serum factors for the clearance of bacteria and colloids in vivo has been demonstrated convincingly through studies of opsonin depletion Injection of a large dose of carbon into a mouse causes a marked reduction in the rate of clearance of a second dose given a short time after the first If bacteria are injected instead of carbon the rate of clearance is similarly low Initially the phenomenon was interpreted to indicate saturation of the phagocytic cells by the first carbon dose However Jenkin and Rowley (1961) showed that it is not the capacity of the phagocytes which is exhausted but the amount of available opsonin in the circulation Opsonization of the bacteria or the carbon with fresh serum in vitro resulted in their prompt clearance from the blood on injection into opsonin-depleted animals

DECOMPLEMENTATION The role of complement or other heat labile factors in opsonization has been particularly difficult to establish One approach to the problem involves the use of avian antibody as sensitizer Avian antibodies bind mammalian complement rather poorly Bacteria sensitized with this antibody and then injected into animals should be cleared less efficiently than bacteria coated with mammalian antibody provided that complement has an opsonic function in vivo That this is so has been demonstrated by Benacerraf and Miescher (1960) A more direct approach involves decomplementation of the animals which are going to be subjected to phagocytosis studies Injection of heat aggregated γ globulin into the peritoneal cavity of mice is followed by a drop in serum complement activity to less than 5 per cent of the original value within 2 hours (Biozzi and Stiffel 1962) In such animals the rate of clearance of antibody coated *E coli* and of sensitized

cytosis promoting activity of serum mention should be made of still another important aspect A prerequisite for engulfment of harmful microbes is their recognition by phagocytic cells It is well known that mammalian leukocytes migrate actively toward clumps of bacteria and immune precipitates Apparently, certain diffusable substances are produced in the course of immune reactions which are instrumental in attracting these cells Although the nature of this material is still enigmatic some clues have been obtained recently Boyden (1962) found that antigen antibody complexes *per se* exert no chemotactic effect on rabbit polymorphonuclear leukocytes in vitro however on interaction of these complexes at 37° C with fresh serum the active principle is generated It is heat stable and nondialysable Since it is produced only from fresh and not from previously heated serum it might be derived from complement

In vivo experiments on rats also suggest that complement fixation is essential for the attraction and the accumulation of neutrophils in the tissue (Ward and Cochrane 1964) In normal animals deposition of immune complexes in the vessel walls leads to the infiltration of neutrophils and the development of Arthus vasculitis In animals decomplemented with aggregated γ globulin or antibody against rat β_{1C} globulin an Arthus reaction could not be elicited Polymorphonuclear leukocytes were not attracted to the deposited antigen antibody complexes Inhibition of the reaction was correlated with lack of complement binding in the tissue

IMPAIRMENT OF HOST RESISTANCE DUE TO HEREDITARY DEFECTS

Congenital Agammaglobulinemia in Man

The disease was first described by Bruton (1952) and since has been investigated extensively (Good and Zak 1956 Good *et al* 1962) Afflicted patients exhibit gross deficiency in plasma cells and absence of γ globulin from serum Immunoelectrophoresis has disclosed lack of all 3 major γ globulins 7S γ globulin 19S γ globulin and β_A globulin (Gitlin *et al* 1956) Isolated deficiency in 19S γ globulin and β_A globulin in the presence of a normal concentration of 7S γ globulin has also been observed (Gideon *et al* 1957) Family studies suggest that the disease is due to an inborn error of metabolism transmitted as a sex linked recessive trait

The main clinical feature of the disease is an increased susceptibility to bacterial infections These are primarily due to *Staph aureus* pneumococci, streptococci meningococci and *H influenza* These patients die of infection if not protected by frequent administration of pooled γ globulin

Congenital Complement Deficiency in Rabbits

In 1961 Rother and Rother reported the occurrence of a recessively inherited complement defect in rabbits Analysis of the serum revealed the absence of one of the factors of the classic third component of hemolytic complement The identity of the deficient factor has not been determined but it must be either C 3 C 5 or C′6 since incubation of the serum with sensitized cells yields a rapidly decaving EAC′1a 4,2a complex Immunoelectrophoresis and starch gel electrophoresis indicate the lack of a β globulin which has not been characterized in detail The serum of deficient animals is devoid of bactericidal activity although antibody production appears to be unimpaired An Arthus reaction cannot be elicited unless exogenous complement is supplied Despite continuous efforts to increase the number of these interesting animals only a few are alive at present because of the high mortality rate during the first 2 weeks after birth (Rother personal communication)

Phagocytic Cells

INTRODUCTION AND HISTORICAL ASPECTS

It is difficult or impossible to identify the discoverer of phagocytic cells or the precise date of their discovery In the mid 1800 s mammalian tissues and fluids were studied extensively under the microscope among the types of cells recognized were some which exhibited locomotion and showed a tendency to engulf foreign particles in their environment For many years these ameboid cells were thought to function as scavengers serving to carry away debris introduced into tissues It was also widely held that they accounted for spreading infectious diseases by ingesting and transporting microbes

Precise staining procedures introduced by Ehrlich enabled the classification of ameboid blood cells into several types including neutrophils eosinophils and monocytes Studies by von Recklinghausen Aschoff and others on the localization of vital dyes injected into animals led to the recognition of two groups of large ameboid cells in tissues one freely wandering and the other apparently fixed to the inner linings of small vessels in organs such as the liver the spleen and lymph nodes

Elie Metchnikoff a zoologist by profession began his classic studies on these ameboid cells of animal tissues in 1882 It was he who gave them the name phagocyte derived from the Greek for eating cell Metchnikoff s great contribution for which he shared the Nobel Prize with Ehrlich in 1908 was the discovery that phagocytes were not mere scavengers but rather constituted one of the principle agencies of host resistance against microbial invaders (Metchnikoff 1892 1905) Metchnikoff observed closely a variety of experimental infectious diseases ranging from inoculation of a yeast like microorganism into daphnia a tiny crustacean to the introduction of anthrax bacilli into mammals and concluded that the outcome—disease or no disease—was determined largely by the interaction between the microbes and the phagocytic cells of the host As a rule whenever phagocytes accumulated about the injected microorganisms and engulfed them no disease followed whereas inoculation of microbes that resisted the phagocytic attack resulted in fulminating infectious disease

Metchnikoff's concept of the role of phagocytes in host resistance to sepsis has been amply confirmed In this chapter we shall review the current state of knowledge of the biology and the functions of mammalian phagocytic cells

MORPHOLOGY OF VARIOUS TYPES OF PHAGOCYTIC CELLS

Phagocytic cells have been classified into various types on the basis of their morphology and staining reactions on exposure to mixtures of acid and basic dyes

eral groups monocytes and macrophages Monocytes are slightly larger than granulo cytes and in stained preparations show an oval or horseshoe shaped nucleus and abundant basophilic cytoplasm with fine azuro philic granulations Macrophages vary con siderably in morphology depending on their tissue localization and physiologic status These morphologic differences have been studied extensively (Maximow 1932) and have led to a multitude of names for the various types of cells—histiocyte clasmato cyte Kupffer cell alveolar macrophage or dust cell and so on These cells share general morphologic features such as large size round or oval nucleus and abundant baso philic cytoplasm with variable granularity Differences between these macrophages are brought out on supravital staining or on study of their ultrastructure

Living phagocytic cells observed under phase contrast optics are shown in Figure 1 The migrating human neutrophil and eosinophil both show a ruffled border or pseudopod at the leading edge and con striction into a tail like structure at the rear often with thin cytoplasmic strands extending from the trailing edge Granules in the cyto plasm are tiny and indistinct in the neutro phil but are well visualized in the eosinophil Nuclear lobes are homogeneous or slightly mottled in appearance A rabbit alveolar macrophage is shown in the lower portion of Figure 1 Among the distinguishing fea tures are the large size the ruffled membrane with microvillous projections and the large number and variety of cytoplasmic formed elements Small granules of macrophages commonly are gathered in the perinuclear region forming a rosette pattern about the centrosphere region Various types of large granular elements are located in the periph eral cytoplasm

Electron microscopic features of neutro phils eosinophils monocytes and macro phages are illustrated in Figures 2 and 3 Noteworthy aspects of the neutrophil in clude peripheral condensation of dense ma terial in the nuclear lobes the large num ber of cytoplasmic granules appearing as electron dense homogeneous bodies sur rounded by a membrane and the relative scarcity of other cytoplasmic organelles Eosinophils resemble neutrophils in general their granules are larger in most species and a dense crystalloid structure is commonly seen in the otherwise homogeneous granule matrix The monocyte shows only a few dense bodies or granules in the cytoplasm mitochondria Golgi apparatus and endo plasmic reticulum may be abundant The rabbit alveolar macrophage shown in Figure 10 3 has in its cytoplasm a great number and variety of dense bodies granules and vesicular structures

THE LIFE HISTORY OF PHAGO CYTIC CELLS ORIGIN DISTRIBUTION AND FATE

Neutrophils and eosinophils are both pro duced in the bone marrow from stem cells passing through well known stages of ma turation Myeloblast ⟶ promyelocyte ⟶ myelocyte ⟶ metamyelocyte ⟶ juvenile or stab form ⟶ mature granulo cyte (reviewed by Wintrobe 1962) Early forms are rich in endoplasmic reticulum and show cytoplasmic basophilia These morpho logic signs of protein synthesis disappear as maturation progresses and cytoplasmic gran ules are formed Division of the nucleus into lobes occurs late in neutrophil differ entiation

Use of modern radioactive technics has enabled reasonably precise determination of the distribution and the turnover of neutro phils (Osgood 1954 Bryant and Kelly 1958 Athens *et al* 1961 Brecher *et al* 1962a) Maturation in the marrow from stem cell to fully developed granulocyte re quires 2 to 3 days In a healthy man ap proximately 25 billion neutrophils are cir culating in the bloodstream at a given time A similar number of these cells are margin ated on vessel walls For every circulating neutrophil approximately 100 mature cells are held in the bone marrow reserve pool Neutrophils remain in the bloodstream for 6 to 12 hours and then pass into the tissues by traversing capillary walls Once in tissues they never return to the circulation The life span of neutrophils in tissues is not known precisely but they are end cells incapable of division and probably die or pass into the

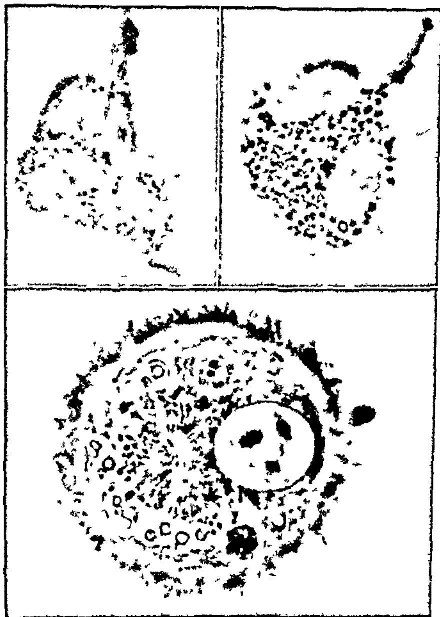

FIG 1 Phase contrast appearance of (*top left*) a human neutrophil (*top right*) a human eosinophil and (*bottom*) a rabbit alveolar macrophage in thin glass coverslip preparations × 2 000 The neutrophil and the eosinophil show a ruffled membrane at the leading edge and a tail like structure at the rear Nuclear lobes and cytoplasmic granules are evident The alveolar macrophage shows myriads of microvillous surface projections Nucleus and nucleoli are well visualized Cytoplasmic structures may be divided into 3 zones (1) a collection of small dense granules arranged in a radiating pattern about the centrosphere region and adjacent to the nucleus (2) a peripheral zone containing large granules and inclusion bodies of varied size and shape and (3) perinuclear small rod shaped structures

Polymorphonuclear phagocytes of 2 types are recognized neutrophils and eosinophils Neutrophils have a nucleus divided into several oval or sausage shaped lobes connected one to another by thin strands of nuclear material Their cytoplasm shows little or no basophilia and contains numerous (50 to 200) tiny granules which do not show a preference for either the acid or the basic stain giving rise to the names granulocyte and neutrophil In some species such as rabbit and guinea pig the cytoplasmic granules are acidophilic thus requiring the term heterophil or pseudoeosinophil For the sake of clarity and convenience in this discussion we shall employ the term neutrophil for all cells of this class

Eosinophil leukocytes commonly show a nucleus divided into 2 lobes shaped like tear drops Their cytoplasm is weakly basophilic Granules in eosinophil cytoplasm have as the name implies a strong affinity for acid dyes The size and the number of eosinophil granules varies markedly from species to species

Mononuclear phagocytes fall into 2 gen

outside world in respiratory or intestinal contents after a few days at most The picture then is one of production of neutrophils in large numbers with dynamic turnover and transportation to the tissues via the blood stream Little is known about mechanisms that regulate the rate of neutrophil production or the rate of release of mature neutrophils from the bone marrow into the blood stream (Gordon *et al* 1960)

Eosinophil life history has also been studied extensively and resembles closely the life history of the neutrophil (Rytomaa 1960) Marrow maturation of eosinophils requires approximately 2 days (Bryant and Kelly 1958) Eosinophils in the bloodstream pass into the tissues within a few hours For every circulating eosinophil there are approximately 200 mature cells in the marrow reserve and 500 eosinophils in tissues The tissues notably rich in eosinophils are intestines skin respiratory tract and vagina i e sites in contact with the outside world Eosinophils are probably incapable of division and survive in tissues for only a few days

Despite extensive study the life history of mononuclear phagocytic cells remains poorly understood Monocytes of the blood may be produced from stem cells in bone marrow or may arise from cell differentiation in lymph nodes or spleen In contrast with the granulocytes mature monocytes have the necessary equipment for various synthetic activities for long term survival and possibly for cell division The life span of circulating monocytes and their fate in tissues is not known

Macrophages include a variety of large mononuclear phagocytic cells distributed throughout various organs and tissues These cells derive from embryonic mesenchymal elements (Maximow 1907) As mentioned above they differ somewhat from one another in morphology but appear to be related functionally as reflected by their ability to concentrate vital dyes and their phagocytic activity (Aschoff 1924) Macrophages occur in particular abundance in liver spleen lymph nodes omentum lung and subcutaneous tissue The numbers and also the activity of macrophages in a given tissue change following various stimuli The exact mechanism underlying this cell proliferation and alteration is not clearly understood in some instances monocytes from blood may emigrate into the tissues and undergo transformation into macrophages (Ebert and Florey 1939) whereas in other situations existing tissue macrophages or primitive cells in lymph nodes or spleen may be stimulated to multiply or to alter their morphology and functional capacity

Macrophages may also transform into large sessile or epithelioid cells under the influences of such agents as tubercle bacilli These epithelioid cells together with giant multinucleated cells thought to arise from fusion or amitotic division of macrophages are prominent features of the granulomatous response seen in certain chronic infectious or allergic conditions

BIOCHEMISTRY AND GENERAL PHYSIOLOGY OF PHAGOCYTIC CELLS

Carbohydrate metabolism of neutrophils has been studied extensively in recent years (reviewed by Karnovsky 1962) These cells derive their energy from the breakdown of glucose or other simple carbohydrates and they carry reserve stores of such nutrients in their cytoplasm in the form of glycogen Even under aerobic conditions neutro

Fig 2 Low power electron micrographs (*Top*) a human neutrophil (*bottom*) a human eosinophil In both cells the nuclear lobes (N) show dense staining peripherally The very small dark dots distributed throughout the cytoplasm are glycogen deposits Neutrophil granules (G) are round oval or rod shaped with a homogeneous dense matrix and a limiting membrane visible in some instances A few of the granules appear to be partially empty Mitochondria and endoplasmic reticulum are sparse or absent The eosinophil granules (G) are large round or oval structures with a denser crystalloid inclusion within them A few mitochondria (M) and many small vesicular bodies are also seen Fixed in phosphate buffered osmic acid embedded in epon double stained with uranyl and lead ions × 17 600

FIGURE 2 (*Caption on facing page*)

FIG 4 An electron micrograph showing a polymorphonuclear leukocyte (1) crawling through a capillary wall The lumen of the blood vessel is at the top The leukocyte has extended a long pseudopod (Ps) between the endothelial cells (E) (From Marchesi V T Quart J Exp Physiol *46* 1961)

phils derive most of their energy from glycolysis not respiration These phagocytes continue to function well in the absence of oxygen or after the addition of cyanide to their environment on the other hand function is blocked by iodoacetate or other inhibitors of glycolysis Neutrophils degrade glucose by the Embden Meyerhof pathway and to some extent utilize the hexose monophosphate shunt They produce large amounts of lactic acid as a result of their glycolytic metabolism A functioning Krebs s cycle has been reported but is not considered to be a major metabolic pathway in the cell Normal neutrophils consume oxygen and possess respiratory capabilities Approximately two thirds of the oxygen uptake is cytochrome linked and presumably associated with mitochondrial activity whereas the remaining oxygen consumption is non-cytochrome linked and apparently reflects the activity of cytoplasmic oxidases

The synthetic abilities of mature neutrophils are largely unknown Although labeled precursors are incorporated into ribonucleic acid neutral lipids phospholipids and pro

---

FIG 3 Low power electron micrographs (*top*) a human blood monocyte (*bottom*) a rabbit alveolar macrophage

The monocyte has a large horseshoe shaped nucleus (N) Stacks of small membranelike structures the Golgi complexes (Go) are prominent The cytoplasm also contains many mitochondria (M) a few dense granules numerous small vesicles and glycogen deposits × 17 600

The alveolar macrophage shows in its cytoplasm many large homogeneous dense granules (G) arranged in a radiating pattern about a clear zone Also seen are dense inclusion bodies (IB) many of which have an onion skin or myelin figure appearance Very small vesicular structures are numerous and endoplasmic reticulum is visible in some regions × 14 000

FIGURE 3 (*Caption on facing page*)

cussed later Phagocytosis and pinocytosis are probably similar processes differing only in the solid or the liquid state of the material engulfed and the size of the invaginated membrane pocket (Holter 1959)

THE INFLAMMATORY RESPONSE

In the sequence of events whereby phagocytic cells function in host defense against infectious diseases the first essential step or series of steps involves mechanisms for establishing contact between these cells and the invading microbes This contact is established in broad terms by one of two means (1) movement of phagocytic cells to the site of bacteria lodged in tissues or (2) movement of bacteria in the lymph or the blood circulation to the site of fixed phagocytic cells of the reticuloendothelial system in certain organs such as lymph nodes the liver and the spleen

Participation of Phagocytes in the Local Inflammatory Response to Microbes Lodged in Tissues

When microorganisms gain entry into tissues there follows a series of changes leading to inflammation with redness swelling heat and pain as the gross signs of this reaction Studies on the microscopic and the biochemical aspects of the inflammatory reaction are too extensive to be considered in general fashion here current knowledge in this field has been reviewed recently (Spector and Willoughby 1963) We shall limit our discussion to the mechanisms whereby phagocytes accumulate in regions of microbial invasion and inflammation

A regular feature of the microscopic appearance of inflamed areas of various types and duration is heavy infiltration with phagocytes Direct continuous observations of the inflammatory reaction in living tissue of the rabbit ear chamber (Ebert and Florey 1939 Allison *et al* 1955) has established clearly that most of the phagocytic cells in these sites come from the bloodstream they pass through the walls of capillaries and move to the infected or the injured area

In the normal capillary vessel red cells usually stream through the central zone whereas leukocytes are seen to tumble along in a relatively clear layer of plasma at the periphery Very soon after injury or the introduction of microbes the endothelial lining of small vessels in the vicinity becomes sticky The exact nature of this change is not known but in any event leukocytes begin to adhere to the wall forming a sort of a pavement lining the vessel (Florey 1962)

White cells adhering to the endothelium crawl about and soon pass through the vessel wall to reach the tissues The precise mechanism by which white cells accomplish this remarkable feat of traversing the apparently intact capillary wall has been studied recently by electron microscopy In experimental pancreatitis endothelial cells seem to send out processes and actually engulf the leukocytes (Williamson and Grisham 1961) Studies have also been done by Marchesi and Florey (1960) and by Marchesi (1961) on phagocytes emigrating through capillaries of the rat mesentery their pictures one of which is reproduced in Figure 4 clearly show the phagocyte sending out a pseudopod to penetrate the junction between endothelial cells This junction ordinarily tightly closed is thus opened whether this opening is accomplished by mechanical forces alone or also involves the secretion of enzymes to dissolve the cement substance remains to be determined

Following their emigration from blood vessels phagocytes congregate in the injured and infected area This accumulation may be based either on chemotaxis i e specific attraction and directed locomotion toward the invading microbes or on random locomotion of phagocytes and immobilization of those cells wandering into the challenge area

During the early stages of an inflammatory response to bacteria neutrophils predominate only a few eosinophils and mononuclear phagocytes being in evidence In prolonged inflammatory reactions such as those due to chronic infection macrophages often constitute a large proportion of the cells present Formerly it was held that neutrophils were specifically attracted to the acutely inflamed area and that macrophages moved in later perhaps as a result of neutrophil degeneration or biochemical changes

tem the net synthesis of these compounds has not been demonstrated (reviewed by Karnovsky, 1962) Enzymes responsible for the synthesis of glycogen are apparently present

Essentially nothing is known concerning metabolic activities of eosinophilic leukocytes

Knowledge concerning the metabolism of monocytes and macrophages is sparse, but it is believed that metabolic pathways similar to those in neutrophils are operative Glucose utilization and oxygen consumption of macrophages are somewhat higher than in neutrophils (Stahelin *et al* 1956) Recent evidence suggests that various types of mononuclear phagocytes may differ in their metabolism For example alveolar macrophages show greater respiratory activity than do the other phagocytic cells and seem to be dependent on an aerobic environment for their function (Oren *et al* 1963)

All 3 types of phagocytic cells contain a number of hydrolytic enzymes which are thought to be concerned with the degradation of ingested foreign material These enzymes include peroxidase alkaline and acid phosphatase acid ribonuclease acid deoxyribonuclease lipases proteinases beta glucuronidase and lysozyme Recent studies on neutrophils (Cohn and Hirsch 1960) eosinophils (Archer and Hirsch 1963a) and macrophages (Cohn and Wiener 1963a) show that these digestive enzymes are contained in or firmly attached to cytoplasmic granules of the phagocytic cells Therefore these granules can be considered to be a form of the *lysosome* originally described by de Duve in rat liver homogenates (de Duve 1955 Novikoff 1961)

The physiologic functions of granulocytes and macrophages center about surface phenomena resulting in locomotion phagocytosis and pinocytosis

Neutrophils and eosinophils show active ameboid movement when placed in warm chambers Locomotion can be quite rapid ranging up to 40 microns per minute (cited by Dittrich 1962) Monocytes and macrophages move about slowly or not at all under in vitro conditions but do show undulating movements of their membranes After prolonged culture on glass surfaces they commonly assume a stellate shape Mononuclear phagocytes observed in tissues move slowly

All 3 types of phagocytic cells move toward or away from certain objects or substances in their environment a phenomenon termed chemotaxis Chemotaxis of leukocytes has been studied for nearly a century Many of the studies on this phenomenon have led to fallacious conclusions based on technical artifacts (Harris 1954 1959), but it is true that once within range (usually 100 microns or less) of suitably attractive objects phagocytic cells of all types abandon their random locomotion and move in a straight line toward the object The precise mechanism involved in this sensory response of phagocytic cells remains unknown (McCutcheon 1955) Most authorities have proposed the existence of a concentration gradient of chemical nature about the particle this gradient being based either on the liberation of some substance from the particle or on adsorption onto the particle of a component of the micro-environment Also possible but unsupported by experimental evidence is a mechanism whereby a single leukocyte first encounters a particle by chance and then as a result of this encounter liberates a chemical messenger to call other phagocytes to the area Chemotaxis to bacteria such as staphylococci apparently operates in the absence of serum (cited by Florey 1962) On the other hand recent studies by Boyden (1962) indicate that chemotaxis of antigen antibody precipitates requires the presence of fresh serum The precipitates are not themselves chemotactic but rather interact with heat labile serum factors to produce a heat stable substance which attracts white cells

Pinocytosis first described by Lewis (1931) in cultures of macrophages consists of tiny invaginations of undulating surface membranes to form long thin channels extending into the cell these pinch off resulting in the formation of cytoplasmic vesicles containing fluid from the environment (Chapman Andresen 1962) Mammalian phagocytes apparently employ pinocytosis for the bulk transport of both small and large molecular weight solutes The analogous process by which solid particles are taken into the cell phagocytosis will be dis

the ingestion process and the role of leukocyte metabolism in particle uptake Under conditions in which fully susceptible bacteria are presented to phagocytes in an optimal environment it is possible to block the ingestion process by introducing certain metabolic inhibitors Studies with polymorphonuclear leukocytes clearly indicate that compounds which block the glycolytic pathway also destroyed the capacity of the cell to carry out particle ingestion (Sbarra and Karnovsky 1959 Cohn and Morse 1960a) In contrast phagocytosis is not prevented by factors which depress respiration such as an anaerobic environment cyanide or antimycin A Similar metabolic requirements for phagocytosis have also been found for peritoneal macrophages of various animals (Oren *et al* 1963) However the alveolar macrophage appears to depend on both the respiratory and the glycolytic pathways for its function

The susceptibility of bacteria to phagocytosis varies widely depending on the physicochemical nature of their surface which apparently determines whether or not fixation to phagocyte membrane can occur From this point of view microbes can be divided into 3 groups (1) a group of avirulent rough strains exemplified by rough pneumococci and some streptococci possessing no M protein or hyaluronic acid capsule whose surface apparently requires no modification in order for attachment to phagocytes to occur (2) strains such as *Staphylococcus albus* or some coliforms which are not taken in unless they have been coated either with heat labile serum factors or with antibody and (3) potentially virulent encapsulated microbes whose surface enables them to ward off phagocytosis under many conditions unless this surface is altered by reaction with specific antibody (Hirsch and Strauss 1964) The nature of the antiphagocytic surface material may be carbohydrate protein or both as illustrated by the polysaccharide capsule of pneumococci the M protein and hyaluronic acid of streptococci the polyglutamic acid capsule of anthrax bacilli or the surface factor of some strains of *Staphylococcus aureus* (see chapters on these microbes in this volume) Thus clearly established is the prime importance in phagocytosis of serum factors of antibody and/or complementlike nature collectively known as opsonins Efficient operation of host resistance in this regard requires the combined action of both humoral and cellular agencies The role of opsonins in promoting phagocytosis has been demonstrated in vitro under various conditions and also in the clearing of bacteria from tissues or the bloodstream of living animals (reviewed by Rowley 1962)

A variety of other environmental factors influence the kinetics of phagocytosis These include salt concentration pH divalent cations and temperature (Mudd *et al* 1934 Chernew and Braude 1962) In most instances the changes in the medium required to impair phagocytic function significantly are drastic and far removed from physiologic conditions Phagocytosis proceeds quite well over a rather wide range of hydrogen ion concentration say pH 6 to 8 A variety of reagents which chelate divalent cations block phagocytosis these cations are apparently necessary for normal cell function and perhaps also play a role in attachment of microbes to cell membrane Salt concentrations of the medium somewhat lower than the physiologic level actually increase the rate of phagocytosis In contrast when the ionic strength is increased to approximately twice that of physiologic solutions particle uptake is blocked

In addition to chemical composition the physical nature of the environment also plays a prominent role in phagocytosis This is illustrated best by the process of surface phagocytosis as described by Wood and associates (1951) These investigators found that leukocytes in a structured environment sometimes were able to engulf encapsulated bacteria in the absence of antibody in contrast with the lack of ingestion in glass systems in vitro Direct observation of this process reveals that the phagocytes trap or cover the microorganisms on suitably rough surfaces and proced to engulf them A similar process called intercellular phagocytosis occurs in dense suspensions of leukocytes in which surrounding cells serve as the trapping surfaces

Another type of reaction which bears some resemblance to surface phagocytosis is the

associated with the evolution of the reaction More precise quantitation of phagocytes in inflammation (Paz and Spector, 1962) has revealed that all types of phagocytes move into the area initially, the macrophage pre dominance later on does not necessarily re flect specific attraction of these cells but rather may be based on death and removal of the short lived polymorphonuclear leuko-cytes in the area and at the same time survival and fixation of macrophages

Some inflammatory reactions due to aller gies or parasitic infestations show eosinophils as the predominant phagocytic cell Antigen antibody complexes may be responsible for the accumulation of eosinophils at these sites (Litt 1961, 1962) Most immune precipi tates attract all types of phagocytic cells but apparently in certain situations, not yet precisely defined specific eosinophilotatic conditions arise

Clearance of Microbes From the Blood or Lymphatic Circulations by Fixed Mononuclear Phago cytes of the Reticuloendo thelial System

In the course of the inflammatory reaction permeability of capillaries and small venules to blood fluids is increased The resulting local edema of tissues leads to distention of the lymphatic channels and an increase in lymph flow Microbes are frequently caught up in this lymph drainage and transported to the regional lymph nodes where they en counter fixed macrophages arranged in a sort of a filtering system Bacteria may be come lodged in the lymph vessel or nodes before they are taken up by fixed macro phages, and cause inflammation—lymphan gitis and lmphadenitis—with an attendant influx of blood phagocytes of all types from adjacent capillaries

Microbes caught in the lymph drainage may escape engulfment by the fixed macro phages in lymph nodes and be carried eventually to the blood In other instances microbes gain entry directly into the blood stream for example as a result of wounds or in cases of inflammation accompanied by necrosis Clearance of bacteria and other particles from blood has been studied exten sively (Halpern *et al*, 1953 Rowley 1962) Removal of microbes from blood is accom plished primarily by phagocytic activity of fixed macrophages in sinusoids of certain organs such as the liver and the spleen Even though they are present in large numbers circulating phagocytes seem to play a rela tively minor role in most instances prob ably because opportunity for contact is limited betwen leukocytes and microbes, both of which are carried along passively in the bloodstream

PHAGOCYTOSIS AND THE ENSUING *INTRACELLULAR EVENTS*

Phagocytic cells play their role in host resistance to sepsis by ingesting and inacti vating microorganisms This function can be separated into 2 stages which have different determinants The first step is the actual engulfment process in which the phagocyte surrounds the microbe by means of pseu dopods and transfers it to an intracytoplasmic locus The second stage comprises the variety of intracellular events both morphologic and biochemical which often result in destruc tion of the microorganism

Extensive discussion of general aspects of the act of phagocytosis and its consequences can be found in the reviews of Mudd *et al* (1934) Suter (1956) and Karnovsky (1962)

Determinants of the Rate of Engulfment of Microbes by Phagocytic Cells

Assuming that contact between phagocyte and microbe has been established various factors determine whether or not the microbe will be engulfed These factors include the metabolism of the phagocyte the nature of the bacterial surface the chemical com position of the extracellular medium and the physical nature of the environment For the sake of simplicity these will be discussed separately although it is obvious that all interact to produce a more complicated pic ture under natural conditions

Originally phagocytosis was thought to be a passive physical process dependent only on the surface tension of the cell and of the particle (Fenn 1921) More recent observations establish the active nature of

ment occurring in the phosphatidic acids (Elsbach 1959 Karnovsky and Wallach 1961) These changes in metabolism are unrelated to the nature of the ingested particle and their mechanism and significance are not clearly understood Tentatively they may be considered to reflect the increased demand for energy associated with the phagocytic process and possibly the synthesis of new lipoprotein membranes

During or shortly after the phagocytic process a most striking morphologic event takes place This is the degranulation phenomenon which occurs in all 3 types of phagocytic cells (Hirsch and Cohn 1960 Archer and Hirsch 1963b Cohn and Wiener 1963b) Intimate morphologic features of the degranulation reaction have been studied in polymorphonuclear leukocytes (Hirsch 1962) Granules lyse only when they come into contact with the wall of the phagocytic pouch or with clear zones resulting from prior granule rupture The upper part of Figure 6 shows on the right a neutrophil degranulated after ingesting many bacilli and for comparison on the left a normal neutrophil with numerous granules The rapidity and the detailed morphology of lysis of individual granules in a chicken neutrophil ingesting 2 yeast bodies is shown in the lower portion of Figure 6 Lysis of an individual granule is a very rapid almost explosive event During degranulation hydrolytic enzymes and antibacterial substances in the granules are liberated in soluble form (Cohn and Hirsch 1960b) and probably are transferred directly into the phagocytic vacuole Electron micro

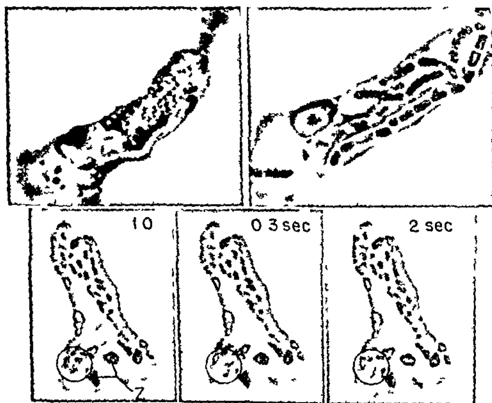

FIG 6 Degranulation which accompanies phagocytosis (*Top left*) A normal neutrophil with its full complement of granules (*Top right*) The neutrophil has engulfed numerous microbes which lie in vacuoles cytoplasmic granules have vanished × 2 000 (*Bottom*) Morphologic and temporal features of granule lysis (in the circled areas) in a chicken polymorphonuclear leukocyte during phagocytosis of yeast cell wall bodies (zymosan Z)

immune adherence phenomenon (Nelson 1953) Certain bacteria in the presence of antibody and complement adhere to the surface of erythrocytes When this occurs leukocytes move about avidly ingesting the immobilized organisms

INTRACELLULAR EVENTS

Following the initial contact between bacterium and phagocyte pseudopod formation is stimulated and contact spreads until at the distal portion of the particle cell membranes from opposite sides meet and fuse The ingested particle is thus confined intracellularly within a pouch or phagocytic vacuole the wall of this pouch being formed by the inverted cytoplasmic membrane of the phagocyte Figure 5 shows (upper row) photomicrographs of a human neutrophil ingesting *Bacillus megaterium* The lower portion of the figure presents the phagocytic process schematically to emphasize the membrane invagination which accompanies particle uptake

During or at the completion of engulfment a variety of metabolic and morphologic events occur which have important effects on both the phagocyte and the ingested particle The majority of studies on the intracellular consequences of particle ingestion have been performed with polymorphonuclear leukocytes although a similar series of events may take place within macrophages

During the process of particle ingestion the phagocyte displays a number of changes in its metabolism The first of these to be studied was a stimulation of oxygen consumption (Baldridge and Gerard 1933) a good portion of which is not linked to the usual electron transfer scheme More recent investigations have demonstrated the stimulation of glucose consumption lactic acid production glycogenolysis and the utilization of glucose by means of the hexose monophosphate shunt (Sbarra and Karnovsky 1959 Cohn and Morse 1960a) In addition there is an increased turnover of neutral lipids and phospholipids with a major incre

microorganisms are destroyed rapidly within phagocytes These susceptible bacteria in clude among others pneumococci strepto cocci staphylococci of both albus and aureus strains klebsiella species and coliforms (Wood 1960) These microbes survive in side neutrophils for only a short time their half life being 7 to 8 minutes Whether or not all forms of macrophages are equally effective or quick in killing ingested bacteria is not known and some recent evidence sug gests that they may differ in this function (Mackaness 1960 Pavillard and Rowley 1962) Little is known about inactivation of bacteria within eosinophils

Our knowledge concerning the intracel lular bactericidal mechanisms is fragmentary A more comprehensive discussion of this field can be found in the reviews of Skarnes and Watson (1957) and Hirsch (1960a) Two bactericidal agents can be extracted from neutrophils of various animals These are lysozyme and a factor called phagocytin Lysozyme was discovered by Fleming (1922) it is a low molecular weight basic protein which acts enzymatically to degrade certain acetylaminopolysaccharides Microbes whose cell wall contains this substrate in form accessible to the enzyme are lysed on exposure to lysozyme Other microbes not susceptible to direct attack by lysozyme are killed on exposure to combinations of this substance and antibody (Amano *et al* 1954) or certain chelating agents (Repaske 1956) Phagocytin has a wide spectrum of activity against both gram positive and gram nega tive bacteria (Hirsch 1960b) It has prop erties suggestive of a basic protein (Zeya and Spitznagel 1963) but has not been iso lated in a pure form as yet Both phagocytin and lysozyme are associated with the gran ules in the normal cell and are liberated at the time of phagocytosis (Cohn and Hirsch 1960)

In contrast with the neutrophil peri toneal macrophages and blood eosinophils contain no phagocytin or lysozyme (Myrvik 1960 Hirsch 1960b Archer and Hirsch 1960a) and alveolar macrophages contain lysozyme but no phagocytin (Myrvik 1960 Cohn and Wiener 1963a) Therefore it is apparent that much remains to be learned about the bactericidal activity of phagocytic cells in particular the mechanism by which macrophages kill microbes remains a mys tery The possible antibacterial role of lactic acid (Dubos 1954 Locke and Rowley 1962) and hydrogen peroxide (Iyer *et al* 1961) produced during metabolism of phag ocytes should be mentioned Recent obser vations (Jenkin 1963) suggest that specific antibody and possibly complement may sen sitize strains of salmonella for killing within macrophages As yet no such effect has been noted for polymorphonuclear leukocytes

Although most microorganisms are rapidly inactivated within phagocytes there are several instances in which this is not the case For example the tubercle bacillus survives within both granulocytes and macrophages *Brucella abortus Pasteurella tularense* some strains of salmonella and *Listeria monocyto genes* have also been reported to survive and multiply within peritoneal macrophages of laboratory animals

Following the bactericidal event suscepti ble bacteria are gradually degraded within phagocytic cells This observation was made initially by Metchnikoff (1905) on morpho logic grounds and has been documented repeatedly by subsequent investigators In gested microorganisms soon lose their baso philia and in some instances their struc tural integrity More exact biochemical information indicates that degradation of bacterial macromolecules takes place rap idly and that in some instances the phagocyte can use these products as substrates for its own synthetic or metabolic processes (Cohn 1963) The rate and the extent of digestion of bacteria are similar within neutrophils and macrophages In the course of this intra phagocytic digestion bacterial toxins and antigens may be destroyed at least in some instances (Walsh and Smith 1951 Cohn 1962a)

Thus far our discussion has been related primarily to the influence of phagocytes on the ingested microorganism In some cases however bacterial products affect phagocytes adversely Although many bacterial products can damage phagocytic cells only a few have this effect in high dilution For example some strains of *Streptococcus pyogenes* pro duce streptolysins whose effect on phago cytes has been investigated recently (Hirsch

FIG 7 Electron micrograph of a rabbit polymorphonuclear leukocyte soon after ingestion of zymosan particles (Z) At two points indicated by the arrows the membrane surrounding the engulfed particle is seen to be continuous with membranes about cytoplasmic granules indicating that membrane fusion accounts for discharge of granule contents into the phagocytic vacuole × 32 000 (Zucker Franklin D and Hirsch J G J Exp Med 1964)

graphic studies suggest that this transfer is accomplished by fusion of the granule membrane with the inverted cell membrane surrounding the engulfed microorganism (Lockwood and Allison 1963 Zucker Franklin and Hirsch 1964) Figure 10 7 shows the discharge of the contents of the granule into the phagocytic pouch shortly after a neutrophil has ingested yeast cell wall (zymosan) particles

Studies on the fate of bacteria within phagocytic cells have been performed in vitro for the most part and with a variety of experimental systems One of the most direct of these has been described by Wilson *et al* (1957) the viability of strains of streptococci has been determined within individual cells at various times after ingestion by human neutrophil leukocytes Other techniques in which the over all fate of bacterial populations can be investigated have been described for neutrophils (Cohn and Morse 1959) and macrophages (Rowley 1960) In general the vast majority of common

Patients with diabetes mellitus seem to be unusually susceptible to certain bacterial diseases and the acidotic experimental animal has clearly lost its ability to ward off certain fungal agents Although the mechanism is not fully understood a delayed and inadequate phagocytic reaction is seen in the tissues of the challenged animal in diabetic acidosis (Sheldon and Bauer 1959)

The unusual susceptibility to bacterial invasion of the renal medulla has been noted in various clinical and experimental situations Recently it has been found that the phagocytic response to lodgement of microbes in the medulla of the kidney is considerably delayed as compared with that in the cortex or other tissues (Rocha and Fekety 1964) Furthermore when leukocytes finally emigrate into medullary tissue their phagocytic ability may be impaired by the high salt concentration likely to be present (Chernew and Braude 1962) or by the fact that ammonia produced in the kidney inactivates the 4th component of complement and destroys opsonic factors required for efficient ingestion of the bacteria (Beeson and Rowley 1959)

Functions of Fixed Phagocytic Cells in Clearing Bacteria From the Blood or the Lymph Circulation

The functioning of fixed macrophages in the blood and the lymphatic streams does not involve a long chain of events as described above for tissue clearance Bacteria are carried to the phagocytes by blood or lymphatic flow therefore variations in function involve primarily the numbers of filtering cells and the efficiency of their individual performance

Quantitative methods have been developed for measuring the rate of bloodstream clearance of carbon particles or labeled bacteria by the reticuloendothelial system This removal rate is influenced by many factors including the size of the particles and the presence of opsonins (reviewed by Benacerraf and Miescher 1960 and by Rowley 1962)

Clearance can be blocked or severely impaired by the injection of large amounts of certain materials such as bacterial lipopolysaccharide Thorotrast or colloidal sulfur In some instances such blockade may reflect inadequate function of overstuffed macrophages Some evidence also suggests that the less efficient phagocytosis under these circumstances may be based at least in part on depletion of opsonic factors following injection of large amounts of these colloid materials

Following the period of blockade the clearance rate not only returns to normal but often is for a time considerably faster than normal This stimulation of fixed phagocytic activity is accounted for by an increase in the number of these cells and also an increase in individual cell performance (see Rowley 1962) Higher than normal levels of circulating opsonic factors may also contribute to the efficiency of reticuloendothelial clearance at this time

In many instances the resistance of experimental animals to bacteria inoculated intravenously is found to be directly related to the efficiency with which the reticuloendothelial system is functioning

The Phenomenon of Acquired Cellular Immunity

Although the majority of the common pathogenic and saprophytic bacteria are handled effectively by phagocytic cells certain organisms are able to survive in the intracellular environment Furthermore with many of these microbes it can be demonstrated that serum antibody plays no important opsonic or bactericidal role However the animal previously exposed to such organisms often acquires a relative immunity to reinfection In order to explain this form of resistance the concept of *cellular immunity* has been invoked Work on this subject has been done with only a few intracellular parasites i e tubercle bacilli brucellae *Pasteurella tularense* and *Listeria monocytogenes* and generally has been limited to observations on their interaction with mononuclear phagocytes At the present time there is no evidence that neutrophils or eosinophils from immunized animals behave differently from cells of the normal animal

On reinfection tubercle bacilli do not multiply and may even be destroyed in contrast with the growth of the microbes seen

et al 1963) These hemolytic proteins kill polymorphonuclear leukocytes apparently by lysing their cytoplasmic granules and liberating digestive enzymes into the cytoplasm of the cell with ensuing autolysis Comparable studies by Woodin (1962) on the action of staphylococcal leukocidin have shown a similar effect However, the importance of these substances in determining the pathogenicity of these organisms has not been established

The complex lipopolysaccharide endotoxins of gram negative bacilli alter the activity of both mononuclear and polymorphonuclear phagocytes In low concentrations these substances enhance the rate of phagocytosis and of glycolysis whereas at higher levels they inhibit these parameters as well as the migration of cells from buffy coat explants (Cohn and Morse 1960b Rowley 1960)

FUNCTIONS OF PHAGOCYTIC CELLS

Role in Combating Microbial Invaders in the Tissues

The function of phagocytes in response to microbes introduced into tissues involves a rather lengthy chain of events production of mature polymorphonuclear leukocytes or mononuclear phagocytes from precursor cells in bone marrow or extramedullary sites delivery of adequate numbers of these cells to the blood margination and emigration from capillaries in or near the invaded tissue *locomotion and perhaps directed movement* toward the microbes phagocytosis transfer of bactericidal agents and hydrolytic enzymes from lysosomal granules to the phagocytic pouch or vacuole killing and digestive attack on the microbes and finally egestion excretion or utilization of the degraded microbial products

It should be emphasized that weakness in any link of this chain of events can result in an inadequate over all phagocytic performance and diminished resistance to infectious disease A few examples of naturally occurring or experimental abnormalities of phagocytic function and host resistance may help to make the point

Perhaps the role of neutrophils in host resistance to infectious diseases is illustrated best by the notorious susceptibility to sepsis of individuals afflicted with agranulocytosis a disorder in which neutrophil production in the marrow is blocked by toxic or allergic reactions

Following massive exposure to x irradiation, circulating neutrophils fall to low levels or even disappear and resistance to bacterial invasion is reduced markedly (Brecher *et al* 1962b Cohn 1962b Smith *et al*, 1963) The scarcity of phagocytic cells almost certainly accounts in part for susceptibility to infectious agents in this situation however other host resistance mechanisms such as anatomic barriers and antibody production are also altered following irradiation

Many forms of leukemia and blood dyscrasias are associated with enhanced susceptibility to bacterial disease Total numbers of circulating leukocytes may be higher than normal in some of these conditions but the bulk of the cells are immature These immature leukocytes are grossly deficient in their ability to emigrate from the blood stream (Rebuck *et al* 1961) and to phagocytize microorganisms (Jersild 1948)

Patients given large doses of certain adrenocortical steroid hormones are unusually prone to develop infectious diseases Latent microbial agents or avirulent species may produce sepsis in this setting Cortisone administration leads to an increase in numbers of circulating functionally normal neutrophils (Hirsch and Church 1961) *However under the influence of cortisone* the inflammatory process is severely suppressed or retarded the hormone apparently interferes with margination emigration and accumulation of phagocytic cells at the challenge site (Germuth 1956 Cohn 1962b) Furthermore suppression of antibody formation by these steroids and alterations in the local biochemical environment in tissues may contribute to the change in host resistance

Other agents such as levans (Shilo 1962) endotoxins (Cohn 1962b) and epinephrine (Miles 1956) act locally to block or retard the influx of phagocytic cells into tissues or body cavities and thus favor markedly the survival of microbes introduced into the affected area

of Arthus reaction sites (Daems and Oort 1962) thus autolytic enzymes released from the granules might conceivably cause local tissue necrosis or extension of the inflammatory process

A specific function for eosinophils in the inflammatory site has also been proposed Eosinophil granules contain in addition to hydrolytic enzymes substances capable of blocking the action of histamine (Kovacs 1950 Vercauteren and Peeters 1952) and of serotonin and bradykinin (Archer and Broome 1963) These 3 materials are responsible at least in part for increased vascular permeability in the inflamed area (Spector and Willoughby 1963) Therefore it is proposed that eosinophils play a homeostatic role serving to counteract or limit the effects of vasoactive substances

Finally to be mentioned is the role of phagocytic cells in general host responses to sepsis (see Chap 13) the best example of such a role being the release from neutrophils of a fever producing agent endogenous pyrogen (reviewed by Atkins 1960)

following the initial challenge Studies by Lurie (1942) indicate that this inhibition of multiplication in the immunized animal is related to a property of its mononuclear phagocytes Suter (1953) found, in a tissue culture system that macrophages from immunized animals inhibit the intracellular multiplication of virulent tubercle bacilli whereas these bacteria multiply freely in cells from normal animals Sera from normal and vaccinated animals do not differ detectably in their effect on the fate of mycobacteria in this type of in vitro system Employing a slightly different technic Mackaness (1954) obtained contrary results namely that prior vaccination does not alter the rate of myco bacterial multiplication within macrophages of the rabbit It should be stressed that in none of these experiments do the immune macrophages have a lethal effect on the bacilli

Similar experiments employing strains of *Brucella abortus* have been reported by 2 groups of investigators (Pomales Lebrun and Stinebring 1957 Holland and Pickett 1958) In both cases macrophages from immunized animals inhibit the multiplica tion of virulent organisms

Perhaps the most conclusive studies on the topic of cellular immunity are those reported recently by Mackaness (1962) using a system of mouse macrophages and *Listeria monocytogenes* Peritoneal macro phages from the normal mouse allow mul tiplication of a virulent strain In contrast the infection of the animal with small num bers of viable bacteria results in a marked increase in the resistance of the peritoneal cells on the 4th day At this time 90 per cent of these cells rapidly inactivate an inoculum of listeria

The specificity of this reaction has been studied subsequently by Mackaness (1964) Employing *Brucella abortus* as an infecting agent, it was possible to demonstrate that peritoneal macrophages became resistant to an in vitro challenge with listeria Since there is no known immunologic relationship be- tween the two strains this implied that the macrophage alteration was nonspecific However little is known concerning the mechanism of this change nor is there ade quate data relative to the size of the macro- phage pool in the sensitized animal These questions are currently under investigation in a number of laboratories

Functions of Phagocytic Cells Unre lated to Their Interaction With Microbes

Of course phagocytic cells do play a role as scavengers that is to say, they engulf nonmicrobial foreign material and digest it or sequester it within their cytoplasm or transport it to the outside world in intestinal and respiratory tract secretions Phagocytes also ingest damaged tissue cells and effete erythrocytes the destruction of red blood cells being primarily an activity of macro phages in the spleen and the liver (Muir and Niven 1935)

Much work has been done concerning possible relationships between phagocytes and antibody production or destruction As mentioned earlier some antigens apparently are degraded within neutrophils to such an extent that they are no longer immunogenic On the other hand eosinophils (Speirs 1958 1963) or macrophages (Fishman 1961 Fishman and Adler 1963) are thought by many to play an essential role in preparing antigen in transporting antigen to the potential antibody producing cell or even in producing antibody directly

Antigen antibody complexes may exert harmful effects on host tissues Since phago cytic cells are capable of engulfing and di gesting immune precipitates (Sorkin and Boyden 1959 Cochrane *et al* 1959) they may well function to protect against these harmful effects Eosinophils seem to be par ticularly prone to accumulate about antigen antibody complexes (Litt 1961 1962) and do ingest these complexes (Sabesin 1963) degranulating during the process (Archer and Hirsch 1963b)

In some instances phagocytic cells in the inflammatory area may be responsible for damage to host tissue as well as to the microbial invaders For example Arthus or Shwartzman reactions are suppressed or even blocked in the neutropenic animal (Stetson and Good 1951 Humphrey 1955) Degranulation of neutrophils has been noted in electron microscopic studies

TABLE 1 TYPES OF ALLERGIC INFLAMMATORY RESPONSES IN MAN*

	IMMEDIATE TYPE	
	WHEAL AND-ERYTHEMA†	ARTHUS-TYPE
Clinical state	Hay fever asthma Serum sickness Purpura Physical allergies Some infectious allergies Penicillin rashes	Serum sickness Erythroblastosis Purpura (drugs) Glomerulonephritis ? Rheumatic fever ? Rheumatoid arthritis ? Periarteritis nodosa ??Agranulocytosis ??Ulcerative colitis
Sensitizing materials	Pollen molds kapok danders Antibiotics a few drugs special allergens (ascaris toxoid horse serum etc) Altered tissues of the individual (physical allergies)	Soluble proteins Drugs antibiotics Polysaccharides of bacteria and parasites Erythrocytes (Rh positive) ? (unknown materials)
Antibody	Present in serum Nonprecipitable Heat labile	Present in serum Precipitable Heat stable
Transfer of sensitivity	With serum	With serum
Cytotoxicity of antigen for sensitive explanted cells	None	None

	DELAYED TYPE	
	MICROBIAL HYPERSENSITIVITIES	NONLIVING AGENTS
Clinical state	Tuberculosis tularemia brucellosis Lymphogranulomatosis smallpox mumps Histoplasmosis and other mycoses Trichinosis	Cutaneous rashes (Allergic contact type dermatitis) Homograft rejection ? Multiple sclerosis ? Thyroiditis
Sensitizing materials	Bacteria viruses fungi parasites	Poison ivy plant oils simple chemicals plastics antibiotics etc Histocompatibility antigens Altered tissues ?
Antibody	Not found in serum Not found within cells	
Transfer of sensitivity	With cells not with serum	
Cytotoxicity of antigen for explanted sensitive cells	Present	

* Adapted from Lawrence H S 1956 Am J Med 20 428-447

† Urticaria gastrointestinal disturbances angioneurotic edema and eczema although immediate type allergies may not exhibit cutaneous reactivity or presence of reagins Foodstuffs often represent the offending allergens The position of infantile eczema is undetermined

MERRILL W CHASE, PH D
The Rockefeller Institute

11

The Allergic State

The term allergy designates an altered reactivity of the tissues toward particular substances as judged from previous experiences of a given individual with the same material or from the norm provided by other individuals of the same species * This definition must exclude the occasional instances of idiosyncrasy in which one encounters an inherent qualitatively abnormal reactivity toward physiologically active materials e g morphine Allergy as seen in man includes a wide variety of manifestations—serum sickness hay fever and asthma allergy to foods infantile eczema poison ivy dermatitis sensitivity to antibiotics and synthetic drugs and sensitivity to products of microbial origin such as tuberculin

The inciting substances indeed various in nature *induce the altered reactivity in the host* following penetration by ingestion absorption through mucous membranes or through skin mechanical injection or invasion of the tissues by pathogenic microbial *or viral or parasitic agents*

The allergic or hypersensitive state may be viewed as *an acquired capacity of the body to react against antigen* Reactions of hypersensitivity are then the outcome of what we may term *the immunologic apparatus* interacting with antigen in the presence of tissues or cells and *allergic inflammation is the common response*

To take the broadest example every animal that has received injections of a foreign protein is potentially an allergic individual for suitably tested it can exhibit anaphylactic shock or inflammatory responses at sites of intradermal injection and in addition a release of histamine and various physiologically active substances can be shown

Allergic reactions that are mediated by circulating antibody commence at once upon the formation of antigen antibody complexes and in this sense can be called immediate with regard to the time of inception of the reaction although a longer period may be required before the physiologic disturbance *has reached its maximum* Typical examples would be allergic rhinitis (hay fever) anaphylactic shock reactions of Arthus type serum sickness and experimental glomerulonephritis (Table 1) The types of *antibody that are concerned vary* as will be described below

Another major category of allergic reactions shows no obvious relationship to circulating antibody The time-course is such *that reactions become apparent only after* several hours and the maximal reaction is reached after 1 to 2 days or longer The term delayed type reactions has been applied to these tissue responses which appear to be attributable to special properties of the white cells probably of the lymphocytic series

* The term is used here in the original sense of von Pirquet (1906) who introduced it to cover all changes induced in the state of reactivity in consequence of contact with any living thing or inanimate substance

vary in their relative combining affinity (avidity) for their specific antigen First formed antibody is generally of low avidity binding with antigen but dissociating from it with fair ease With further antigenic stimulation antibody appears that is increasingly more avid Again while antibodies usually have more than one combining site and are able to bind antigenic molecules in a lattice work that eventually precipitates some classes of antibodies bind to only one molecule of antigen and consequently do not build up a precipitating complex these have been called univalent antibodies Certain Rh human antibodies for example attach to red cells but must be detected by agglutination with antihuman globulin in the indirect Coombs test

Consequently the antibodies operative in reactions of the immediate type of hypersensitivity all attuned in some measure to their inciting antigen fall into several classes However in anaphylaxis and the Arthus reaction we shall be dealing with precipitating antibodies except as specifically noted

ANAPHYLAXIS

Anaphylaxis in its primary sense is an acute *systemic* reaction species characteristic that is exhibited by sensitized animals shortly after reinjection of the same antigen

The word anaphylaxis was coined by Richet in 1902 as a term to contrast with prophylaxis in order to describe a state of *excessive susceptibility* discovered in dogs that he was attempting to immunize with toxic materials Subsequent observations made on guinea pigs by Theobald Smith Otto and many others established that the phenomenon resulted from antigen antibody reactions occurring in vivo For example serum from a guinea pig undergoing active anaphylactic sensitization could sensitize normal guinea pigs (passive transfer)

The symptom complex of anaphylaxis differs with the species such that the physiologic events set in motion by the antigen antibody reaction in vivo appeared to be baffling Some workers held that a soluble anaphylatoxin was set free in the blood stream others that the phenomenon primarily involved tissue cells Subsequent work has revealed that both groups of workers had been dealing with different but valid facets of anaphylactic shock

The discovery of histamine by Sir Henry Dale (1913) gave the first proof of a physiologically active chemical mediator of anaphylaxis The number of skeptics was legion not only was demonstration of its occurrence in all the various species difficult in view of dilution in the circulation and degradation by histaminase but it did not account for all phenomena

Today besides histamine 3 other pharmacologically active chemical materials are known to arise in vivo following antigen antibody combination (Table 2) Histamine and serotonin (5 hydroxytryptamine) both exist preformed in the tissues Two further materials are not preformed but arise *de novo* in consequence of the antigen antibody reaction namely SRS A (Slow Reacting Substance of Anaphylaxis) formed in the tissues and special short peptides plasma kinins that arise by enzymic cleavage of certain plasma proteins The responsible enzymes for engendering SRS A and plasma kinins are bound to fixed tissues (Table 2) and it is not unlikely that they may be held within intracellular granules termed lysosomes (Chap 10) awaiting degranulation by antigen antibody interaction at the cell surfaces

The other preformed substances acetylcholine and heparin appear to play minor roles although release of heparin from mast cells may act to mitigate certain features of shock The active products called anaphylatoxin and leukotaxine are still unknown chemically and it is possible that they may come to be identified with plasma kinins for example

A role has often been pictured for serum enzymes after activation from inactive precursors such as plasmin from plasminogen At least 2 types of serum antiproteases serve to inhibit plasmin (Norman 1957) One serum inhibitor combines rapidly and dissociably with activated plasmin the other more slowly but permanently The net affect is to permit a definite though temporary proteolytic action on suitable substrate Interestingly dilution of fresh guinea pig rat or human serum in glass gives rise in the course of an hour to a nonhistamine permeability factor injection causing a marked

Despite the special and unexpected features that are coming to light through the newer attacks on the problem it still appears likely that the cellular mechanisms of delayed type allergies is immunologic in nature and is connected with the antibody forming apparatus Such allergic responses are characterized by the known immunologic attributes of *specificity* and are capable of *specific desensitization* It is not unlikely that we have to deal with cell bound antibodies of a special sort, perhaps a primitive type of antibody As examples, we may mention dermatitis owing to poison ivy or other contactants and reactions appearing on intradermal testing of patients for current or previous infection when microbial products such as tuberculin or histoplasmin are injected (Table 1)

Owing to these apparent differences in mechanism the 'immediate and the delayed types of allergic reactions will be examined separately Grossly they are not always sharply distinguishable The roles of antibodies and white cells remain rather obscure and allergic excitants can stimulate the immunologic apparatus in both its types of response In clinical tuberculosis for example several circulating antibodies against constituents of the tubercle bacillus appear as *well as delayed type reactivity to tuberculo* proteins

As Table 1 shows some allergic excitants are frank antigens (serum proteins pollen extracts) whereas others are obviously not antigens in their own right Some non antigens (as simple chemical allergens) can be shown to combine with proteins or other substances of the host s tissues as carrier and serve as an artificial antigen at times some alteration in the original structure of the *allergen owing to intermediate metabolism* is probably involved prior to combination It may be helpful to think of antigenic complexes arising from the interaction in vivo between chemical and body constituents as *derivative antigens*

In much the same sense the currently emphasized concept of autosensitization in which an individual is pictured as becoming sensitized to certain of his own tissues probably would require a degradation of native *structure to* the point of incipient antigenicity

The delicate and dynamic balance that exists *in the tissues (homeostasis)* can be upset in ways other than by allergic mechanisms Indeed Roessle has suggested *normergy* to describe the norm of inflammatory responses of normal tissues to a given stimulus *hyperergy* for supranormal reactivity *anergy* for lack of normergic reactivity (owing either to the existence of an immune state or to abnormal cellular physiology) and *hypoergy* has appeared as well commonly to mean a lessened reactivity subsequent to known sensitivity It will be evident that nearly all of the manifestations of allergy are instances of increased levels of reactivity (hyperergy)

Principal emphasis will be given to mechanisms known to be operative in allergic phenomena particularly in animals the *principles then being applied to hypersensitivities* as seen in man *

REACTIONS OF IMMEDIATE TYPE

The allergic responses of animals afford the bulk of our knowledge concerning antigen antibody reactions in relation to tissues Historically, the injection of antigen into actively sensitized animals by the intraperitoneal or the intravenous routes led to *the discovery of systemic shock* (anaphylaxis) whereas injection just below or into the skin led to the finding of *local tissue damage* (the Arthus reaction) Both lines of study have made uniquely additive contributions

The role played by antibodies is proved Immune globulins or antibodies identified as modified gamma β_A and β_{2M} globulins (see Chap 9) are complex in structure and combine with antigen in varying *proportions Some classes of antibodies* over 1 000 000 in molecular weight sediment in a centrifugal field with a speed of 19 Svedberg (19S) units others range around 160 *000 in weight (7S) while some human anti*bodies (reagins) show an intermediate sedimentation pattern somewhat heavier than 7S antibodies Moreover antibodies

* For books presenting special aspects see Lawrence (*1958*) Shaffer LoGrippo and Chase (*1958*) and volumes in the series entitled ***Progress in Allergy*** (Karger New York) and ***Advances in Immunology*** (Academic Press New York)

guinea pig within 10 to 21 days by means of a single injection of soluble foreign protein in the order of 0 1 mcg to 1 mg of crystalline ovalbumin or 0 0001 ml to 0 01 ml of horse serum, preferably injected into the skin With some materials that are less antigenic than native proteins several preparatory injections may be required Because the guinea pig does not form antibody readily and antigens can remain in excess for some time the use of large amounts of native protein antigens can delay appearance of the anaphylactic state for perhaps 6 weeks or more The symptom-complex known as anaphylaxis is demonstrable within 3 to 6 minutes after a 2nd injection of the antigen (0 1 to 10 mg) is given by the intravenous route Alternatively larger amounts may be given by the intraperitoneal route in which case shock often not so acutely manifested starts when enough of the antigen has been absorbed

Within the following minute restlessness is evident the hair especially at the nape bristles often feces and urine are voided the animal scratches at the muzzle with a wiping motion of the forepaws coughs arches its back and raises its head with obvious dyspnea it gives a series of jerks sways goes into violent tonic and clonic convulsions and falls over with cyanosis evident particularly around the muzzle and the ears Death ensues after a few shallow gasps All this occurs often within a period of 3 to 5 minutes Postmortem search reveals firm inflated lungs an actively beating heart active peristalsis and evidences of viceral congestion The trapped air in the lung is seen readily when the organ is cut under water and compressed lightly Coagulability of the blood is found to be decreased

Death from acute shock in the guinea pig is attributable to contraction of the smooth muscle around the secondary and the tertiary bronchioles a prominent anatomic feature in this species The air passages are occluded through infolding of the bronchial mucosa and with lungs remaining distended death results by suffocation Contraction of smooth muscle also explains bristling of hair peristalsis and defecation and contraction of the bladder with involuntary micturition

Lesser degress of anaphylactic sensitivity than the rapidly fatal form described here are to be encountered minimal symptoms include scratching defecation and the characteristic coughs and dyspnea may be transient or not evident

There is another form of shock ("protracted shock") in which dyspnea and bronchoconstriction are much less prominent or even absent this results rather unpredictably usually from subcutaneous or intraperitoneal injection of antigen into the sensitized animal Instead of shock that is explosive in character there is a profound depression at times comalike and oft n with copious tearing accompanied by a marked drop in body temperature (as much as 8° or 9° C) the shock can last for several hours before death or recovery occurs Indeed the guinea pig that exhibits the protracted form of shock instead of acute death is perhaps more informative one sees more drastic changes in blood pressure which after an initial rise falls steadily during the entire period of shock almost complete loss of coagulability of the blood a leukopenia a marked decrease in numbers of blood platelets and a diminution in the titer of "complement (see Chap 9) in the blood owing to fixation by antigen antibody complexes or participation in the activation of plasmin (*vide infra*) When death ensues one observes instead of a ballooning of the lungs edema and hemorrhages of the lungs and congestion of the viscera especially the liver (cf Winter 1945)

In studies of acute shock induced with antigens coupled to radioactive tracers (Warren and Dixon 1948 Dixon and Warren 1950) the antigen causing shock was found to localize around the bronchi particularly in the collagenous tissue between the smooth muscle layer and the cartilage rings this would indicate that specific antibody exists in high local concentration a rather unexpected finding Furthermore these workers found evidence when death failed to ensue until the first 2 to 3 minutes had elapsed of the relaxation of smooth muscle occlusion of the bronchi being then ensured by massive interstitial edema Bradykinin has been demonstrated in guinea pigs undergoing anaphylactic shock reaching a peak at 2½ minutes (Brocklehurst and

but transient increase in the permeability of skin capillaries the substance in guinea pig serum appears to be an α globulin perhaps of protease nature attacking ester linkages meeting in guinea pig serum an α_1 globulin inhibitor (cf Wilhelm 1962) Globulin permeability factor is distinguishable from plasmin but its relation to kallikrein remains unsettled

The relative roles played by these chemical mediators vary from one species to another in relation to amounts available relative sensitivities of a species to particular mediators location of sensitive tissues vis à vis sites of antigen antibody interaction types of antibody and so on For example in the guinea pig we have clear evidence of the *fixation of antibody to tissues with positive* responses obtainable months after antibody *is no longer detectable in the serum a neces*sary period for fixation or equilibration of *passively administered antibody and proba*bly an inhibitory effect of excess circulating antibody in this species histamine in particular appears to play a major role in acute shock although bradykinin may contribute Thus a markedly low susceptibility to anaphylactic shock found in an isologous strain of guinea pig (Wright s Family II) was found to be correlated with a hereditary paucity of histamine in the lung (Stone Liacopoulos Briot Halpern and Neveu to be published) The rabbit in contrast shows only slight evidence of the fixation of antibody to tissues—chiefly in the pulmonary arteries and certain other vessels—but requires circulating antibody in excess *in order* to undergo anaphylaxis Histamine and perhaps serotonin to a degree (Lecomte and Fischer 1958) appears to play the major role in anaphylactic shock *of the rabbit* platelets and basophiles being implicated On the contrary *in sensitized rats in which there* is great insensitivity to histamine (Table 3) *serotonin released from mast cells may* play a relatively important role perhaps *bradykinin also a substance like* SRS-A appears when antigen is injected intraperitoneally Anaphylatoxin shown to be important in dermal reactivity is also produced when *antigen* antibody complexes unite with serum complement The role of the slow reacting substances can be greater in species in which acute shock is not produced quickly

The precipitating feature is union of antigen and serum complement with antibody close to or on the surface of cells It has been suggested that the function of antigen consists in collecting and aggregating gamma globulin molecules such aggregates are pictured as the material causing cellular damage (Ishizaka *et al* 1961) Cells of the vascular endothelium often are affected, becoming swollen apparently phagocytic and permeable allowing rapid development of edema Free and tissue fixed mast cells (Benditt and Rowley 1956 Weiser 1957) and other basophiles (Rorsman Shelley see p 266) are degranulated by antigen antibody *reaction releasing histamine heparin and* varying with the species serotonin Platelets *and white blood cells in the circulation* undergo alterations also becoming attached to the walls *of small vessels and producing* a temporary leukopenia

Heparin preparations have been found to be inhibitory to the release of histamine and serotonin from platelets by thrombin (Humphrey and Jaques 1955) but it appears questionable whether the heparin of basophiles exerts any significant role in the phenomena of hypersensitivity

It is necessary to state that some or all of the end events can be attained in ways that do not require antigen antibody reactions Such phenomena have been termed *anaphylactoid reactions* appearing for example after intravenous injection of bacteriologic peptone or of trypsin or of normal serum either in the pre-clot stage or after incubation *of* serum *with kaolin* starch agar and the like Today as Table 2 shows *we accept the activation* of tissue cathepsins or serum enzymes and their *action on cells and substrates* as the probable pathways Dextran and egg white are known *to release serotonin*

Not all events following combination of antigen with antibody are worked out completely but studies made with the guinea pig are so important that this species will be described in detail

Anaphylaxis in the Guinea Pig The anaphylactic state is readily established in the

guinea pig within 10 to 21 days by means of a single injection of soluble foreign protein in the order of 0 1 mcg to 1 mg of crystalline ovalbumin or 0 0001 ml to 0 01 ml of horse serum preferably injected into the skin With some materials that are less antigenic than native proteins several preparatory injections may be required Because the guinea pig does not form antibody readily and antigens can remain in excess for some time the use of large amounts of native protein antigens can delay appearance of the anaphylactic state for perhaps 6 weeks or more The symptom complex known as anaphylaxis is demonstrable within 3 to 6 minutes after a 2nd injection of the antigen (0 1 to 10 mg) is given by the intravenous route Alternatively larger amounts may be given by the intraperitoneal route in which case shock often not so acutely manifested starts when enough of the antigen has been absorbed

Within the following minute restlessness is evident the hair especially at the nape bristles often feces and urine are voided the animal scratches at the muzzle with a wiping motion of the forepaws coughs arches its back and raises its head with obvious dyspnea it gives a series of jerks sways goes into violent tonic and clonic convulsions and falls over with cyanosis evident particularly around the muzzle and the ears Death ensues after a few shallow gasps All this occurs often within a period of 3 to 5 minutes Postmortem search reveals firm inflated lungs an actively beating heart, active peristalsis and evidences of visceral congestion The trapped air in the lung is seen readily when the organ is cut under water and compressed lightly Coagulability of the blood is found to be decreased

Death from acute shock in the guinea pig is attributable to contraction of the smooth muscle around the secondary and the tertiary bronchioles a prominent anatomic feature in this species The air passages are occluded through infolding of the bronchial mucosa and with lungs remaining distended death results by suffocation Contraction of smooth muscle also explains bristling of hair peristalsis and defecation and contraction of the bladder with involuntary micturition

Lesser degress of anaphylactic sensitivity than the rapidly fatal form described here are to be encountered minimal symptoms include scratching defecation and the characteristic coughs and dyspnea may be transient or not evident

There is another form of shock (protracted shock) in which dyspnea and bronchoconstriction are much less prominent or even absent this results rather unpredictably usually from subcutaneous or intraperitoneal injection of antigen into the sensitized animal Instead of shock that is explosive in character there is a profound depression at times comalike and often with copious tearing accompanied by a marked drop in body temperature (as much as 8 or 9° C) the shock can last for several hours before death or recovery occurs Indeed the guinea pig that exhibits the protracted form of shock instead of acute death is perhaps more informative one sees more drastic changes in blood pressure which after an initial rise falls steadily during the entire period of shock almost complete loss of coagulability of the blood a leukopenia a marked decrease in numbers of blood platelets and a diminution in the titer of complement (see Chap 9) in the blood owing to fixation by antigen antibody complexes or participation in the activation of plasmin (*vide infra*) When death ensues one observes instead of a ballooning of the lungs edema and hemorrhages of the lungs and congestion of the viscera especially the liver (cf Winter 1945)

In studies of acute shock induced with antigens coupled to radioactive tracers (Warren and Dixon 1948 Dixon and Warren 1950) the antigen causing shock was found to localize around the bronchi particularly in the collagenous tissue between the smooth muscle layer and the cartilage rings this would indicate that specific antibody exists in high local concentration a rather unexpected finding Furthermore these workers found evidence when death failed to ensue until the first 2 to 3 minutes had elapsed of the relaxation of smooth muscle occlusion of the bronchi being then ensured by massive interstitial edema Bradykinin has been demonstrated in guinea pigs undergoing anaphylactic shock reaching a peak at 2½ minutes (Brocklehurst and

Lahiri 1962) Possibly bradykinin as well as histamine may contribute to such massive edema Collier *et al* (1960) for example found it usually possible to suppress anaphylaxis by the combined action of an antihistamine (pyrilamine maleate 2 mg/kg) and of aspirin (8 mg/kg) the latter known to mitigate the action of bradykinin on guinea pig bronchioles (aspirin does not antagonize other effects of bradykinin, however)

PASSIVE TRANSFER As mentioned above serum from a guinea pig undergoing active anaphylactic sensitization can passively sensitize normal guinea pigs the recipient animals exhibiting typical anaphylaxis when an injection of antigen is made within the next few days but not before some hours have elapsed

Not only antibody of the guinea pig but in certain instances antibody prepared in other species can sensitize passively e g rabbit The guinea pig is essentially insusceptible to antibody produced by horse cattle chicken or rat Certain human sera can establish passive anaphylactic sensitization—human antitoxic (diphtheric) sera (Neill Sugg and Richardson 1932 Kuhns and Pappenheimer 1952) specimens of serum sickness sera (Longcope and Rackemann 1918 Tuft and Ramsdell 1929) and certain specimens from asthmatic cases (Ramsdell 1930) but human sera containing solely reagins do not do so

Quite recently it has been shown that guinea pig antibodies to soluble protein are separable into 2 types both of molecular weight 160 000 (7S antibodies) but differing in electrophoretic mobility (White Jenkins and Wilkinson 1963 Benacerraf *et al* 1963) Only one of these termed $7S\gamma_1$ appears to be able to fix to tissues and mast cells and give rise to passive anaphylaxis (Ovary Benacerraf and Bloch 1963 cf White *et al* 1963) The other antibody termed $7S\gamma$ seems to arise particularly when certain adjuvants are used Both antibodies are heat stable In the following it must be kept in mind that the quantitative studies cited have been based on total antibody and doubtless adjustments may be in order Likewise it is possible that the similar existence of both slow migrating γ and faster γ_{1A} antibody in mouse horse and so on will yield information on tissue fixation of antibody in these species

The amount of guinea pig antibody that is required to sensitize for fatal anaphylactic shock is extremely small—5 to 30 mcg of antibody nitrogen or less than 0 2 mg of antibody globulin (Kabat and Boldt 1944) The minimal amount of rabbit antibody is of the same order of magnitude—about 30 mcg antibody nitrogen (Kabat and Landow 1942) and 20 mcg of antibody nitrogen has been found to be entirely adequate to ensure maximal sensitization of lung the subsequently isolated lung preparation releasing all available histamine (Liacopoulos *et al* 1963) Rabbit antibody is equally effective whether used as the common precipitating variety or as nonprecipitating or univalent' antibody (Kabat and Benacerraf 1949)

It will be apparent that only a fraction of the administered antibody can become associated with for example a uterine horn removed and perfused prior to use for organ anaphylaxis (*vide infra*) Grabar (1953) has estimated the amount as 0 01 mcg antibody nitrogen

In the guinea pig the anaphylactic state can be inherited from the mother apparently an instance of passive transfer of antibodies as the sensitivity is gradually lost during the first 6 to 10 weeks of life

It has long been known that a latent period of some hours (4 to 18) should be allowed prior to challenge of the passively sensitized guinea pig and from the start the latent period was interpreted as being the time required for fixation of antibody to tissue cells If sufficiently large amounts of immune serum are employed or if one injects soluble preformed antigen antibody complexes prepared in antigen excess (Germuth and McKinnon 1957) no latent period need be observed Benacerraf and Kabat (1949) using quantitative methods and constant antigen found that the amount of antibody needed to result in immediate shock was at least 40 times that required when a 5 hour latent period was allowed and that the sensitizing amount of antibody becomes progressively less as the latent period is extended the minimal shocking dose of antigen decreasing at the same time

Therefore it is understandable that for

passive reversed anaphylaxis in which antigen is injected prior to antibody very large amounts of antibody are required

Passive sensitization can be accomplished by bathing isolated normal tissues in antisera (Dale 1913 Hartley 1939 Kulka 1943 Mongar and Schild 1957a b c Feigen *et al* 1962) including mast cells in pieces of mesentery (Mota 1963) Again the variety of guinea pig antibody that binds to skin and permits PCA tests ($7S\gamma_1$) is the one that sensitizes chopped lung for maximal histamine release $7S\gamma$ proving to be ineffective (Baker Bloch and Austen 1964) The subject has been investigated in detail recently (cf Halpern 1961 Binaghi *et al* 1962) As is seen for sensitization in vivo high concentrations (2 mcg Ab N/ml) of antibody will sensitize in less than an hour but as the exposure time is lengthened increasingly smaller concentrations suffice to attain the same degree of sensitization (0 1 mcg Ab N/ml in 4 hours) In the artificial situation presented here it can be shown that the speed of sensitization is accelerated to a few minutes if the electrolyte concentration is reduced markedly (5×10^{-4}M) or if isotonic nonpolar glucose is used More important it was shown that addition of normal gamma globulin to antibody globulin in the bath (a ratio of 10 1 and higher) reduced the speed of passive sensitization progressively this effect being limited to gamma globulins of those species whose antibody can establish passive anaphylaxis in the guinea pig Likewise the presence of a great excess of nonantibody gamma globulin interferes with passive sensitization with antibody in vivo over a certain time range

Passive Cutaneous Anaphylaxis Instead of inducing passive transfer of the anaphylactic state by means of immune sera injected intravenously or intraperitoneally one may inject intradermally into young guinea pigs (200 to 320 Gm) suitable dilutions of antibody (guinea pig rabbit human) and secure *local* passive sensitization After a suitable latent period such passively sensitized sites can react when antigen is administered systemically or—far more efficiently—intravenously This method of procedure termed Passive Cutaneous Anaphylaxis or simply PCA represents the phenomena of anaphylaxis transposed to and visualized in the dermis (Ramsdell 1928 Chase 1943 1947 Ovary 1951 Ovary and Bier 1953 see review by Ovary 1958) There is an immediate and sharply delimited reaction reaching maximal erythema and edema within 20 minutes and then fading away The technic has been developed chiefly for delicate measurements of antibody (0 03 mcg Ab N/ml or less)

As commonly practiced capillary damage is visualized by mixing with the antigen just prior to intravenous injection dyestuffs that bind to serum albumin—3 5 mg Evans Blue (Ovary) or Coomassie Blue (Feinberg 1963) The local sites develop color within 1 5 to 5 minutes as serum albumin escapes through the injured capillaries the area varying with the concentration of fixed antibody

Just as in passive sensitization in vitro of uterine horn or ileal segment normal gamma globulin can compete with antibody gamma globulin for sites of local fixation along the endothelial wall Hence the technic lends itself best to semiquantitative studies when the concentration of immune globulin in the antiserum is high enough to allow dilution to say 1 30 Further individual differences in capacity to exhibit PCA make it advisable to prepare one site with a standard antiserum of the same specificity as the one under test (Battisto and Chase 1963)

The time for adequate fixation varies with the antiserum Ovary has found standard rabbit antibody to require 4 to 6 hours and Chase has encountered guinea pig antibody that does not react before 9 to 10 hours

Both for passive systemic and for PCA sensitization with guinea pig immune sera there is required the special $7S\gamma_1$ antibody the $7S\gamma_2$ antibody being said not to participate in anaphylaxis but in hemorrhagic Arthus type reactions (p 255) Certain other points deserve mention

(1) Following an intense reaction there occurs a local exhaustion within the area of skin of some component that may not be replaced for as long as 7 days (Chase 1947) probably related to recovery of mast cells (2) Excess antibody introduced into the skin can establish systemic anaphylactic sensitivity and an onset of systemic shock during the test with antigen will negate development of the local reaction (3) Some reactivity remains as long as 5 to 10 days

Lahiri 1962) Possibly bradykinin as well as histamine may contribute to such massive edema Collier *et al* (1960), for example found it usually possible to suppress anaphylaxis by the combined action of an antihistamine (pyrilamine maleate, 2 mg/Kg) and of aspirin (8 mg/Kg) the latter known to mitigate the action of bradykinin on guinea pig bronchioles (aspirin does not antagonize other effects of bradykinin however)

PASSIVE TRANSFER As mentioned above serum from a guinea pig undergoing active anaphylactic sensitization can passively sensitize normal guinea pigs the recipient animals exhibiting typical anaphylaxis when an injection of antigen is made within the next few days but not before some hours have elapsed

Not only antibody of the guinea pig but in certain instances antibody prepared in other species can sensitize passively e g rabbit The guinea pig is essentially insusceptible to antibody produced by horse cattle chicken or rat Certain human sera can establish passive anaphylactic sensitization—human antitoxic (diphtheric) sera (Neill Sugg and Richardson 1932 Kuhns and Pappenheimer 1952) specimens of serum sickness sera (Longcope and Rackemann 1918 Tuft and Ramsdell 1929) and certain specimens from asthmatic cases (Ramsdell 1930) but human sera containing solely reagins do not do so

Quite recently it has been shown that guinea pig antibodies to soluble protein are separable into 2 types both of molecular weight 160 000 (7S antibodies) but differing in electrophoretic mobility (White Jenkins and Wilkinson 1963 Benacerraf *et al* 1963) Only one of these termed $7S\gamma_1$ appears to be able to fix to tissues and mast cells and give rise to passive anaphylaxis (Ovary Benacerraf and Bloch 1963, cf White *et al* 1963) The other antibody termed $7S\gamma_2$ seems to arise particularly when certain adjuvants are used Both antibodies are heat stable In the following it must be kept in mind that the quantitative studies cited have been based on total antibody and doubtless adjustments may be in order Likewise it is possible that the similar existence of both slow migrating γ and faster γ_{1A} antibody in mouse horse and so on will yield information on tissue fixation of antibody in these species

The amount of guinea pig antibody that is required to sensitize for fatal anaphylactic shock is extremely small—5 to 30 mcg of antibody nitrogen or less than 0 2 mg of antibody globulin (Kabat and Boldt 1944) The minimal amount of rabbit antibody is of the same order of magnitude—about 30 mcg antibody nitrogen (Kabat and Landow 1942) and 20 mcg of antibody nitrogen has been found to be entirely adequate to ensure maximal sensitization of lung the subsequently isolated lung preparation releasing all available histamine (Liacopoulos *et al* 1963) Rabbit antibody is equally effective whether used as the common precipitating variety or as nonprecipitating or univalent antibody (Kabat and Benacerraf 1949)

It will be apparent that only a fraction of the administered antibody can become associated with for example a uterine horn removed and perfused prior to use for organ anaphylaxis (*vide infra*) Grabar (1953) has estimated the amount as 0 01 mcg antibody nitrogen

In the guinea pig the anaphylactic state can be inherited from the mother apparently an instance of passive transfer of antibodies as the sensitivity is gradually lost during the first 6 to 10 weeks of life

It has long been known that a latent period of some hours (4 to 18) should be allowed prior to challenge of the passively sensitized guinea pig and from the start the latent period was interpreted as being the time required for fixation of antibody to tissue cells If sufficiently large amounts of immune serum are employed or if one injects soluble preformed antigen antibody complexes prepared in antigen excess (Germuth and McKinnon 1957) no latent period need be observed Benacerraf and Kabat (1949) using quantitative methods and constant antigen found that the amount of antibody needed to result in immediate shock was at least 40 times that required when a 5 hour latent period was allowed and that the sensitizing amount of antibody becomes progressively less as the latent period is extended the minimal shocking dose of antigen decreasing at the same time

Therefore it is understandable that for

Becker and Wirtz (1959) suggested that im mune hemolysis of erythrocytes might offer a useful analogy to allergic events

The same procedure of exposing chopped sensitized lung to antigen or perfusing intact lung with antigen gives rise not only to hista mine but to another pharmacologically active material *Slow Reacting Substance A* (SRS A) (Table 2) Assay is made on guinea pig ileum in the presence of antihista mine drug and atropine Histamine liberation is essentially complete in 5 minutes SRS A appears somewhat later its concentration in creasing for more than 15 minutes Neither platelets nor plasma is required for its pro duction but the synthesis is halted by in terfering with the enzymatic pathway that liberates the preformed histamine Since guinea pig bronchioles are relatively insus ceptible to SRS A this material probably has *no large part in acute shock in this species*

Another pharmacologically active sub stance bradykinin appears in anaphylaxis (Brocklehurst and Lahiri 1962) The action of antigen on sensitized tissue releases a fac tor that acts directly or indirectly to secure enzymic cleavage of plasma α globulins pro ducing a 9 peptide chain which has been synthesized (Table 2) This potent broncho constrictor (cf Collier 1963) has been found to be present within 2 to 5 min utes in anaphylactic shock although it is short lived owing to the action of peptidases The contribution to systemic anaphylaxis of the guinea pig is not determined A general summary is provided in Tables 3 and 4

Anaphylaxis in the Dog Several injections of native protein are usually required to sensitize dogs adequately to prepare for shock although the anaphylactic state may be induced passively by administration of antiserum and reactions can be secured with *out any latent period* (Sherwood *et al* 1946)

Injection of antigen by the intravenous route is followed by restlessness then vomit ing salivation and diarrhea (at times bloody) and finally profound collapse with loss of muscle tone and slow often labored respiration at the same time the blood pres sure and the body temperature decrease markedly As with the guinea pig the re leased heparin causes a loss of coagulability of the blood and there is a decrease in serum complement a pronounced leukopenia in the peripheral blood reflects the elective retention of polymorphonuclear leukocytes in the lung capillaries where masses of white cells adhere tenaciously (Dean and Webb 1944)

In the most acute instances of anaphylactic death necropsy discloses chiefly an enor mously distended and congested liver (in deed it may contain as much as 60% of the blood) for it is the liver that releases the bulk of the histamine (Dragstedt *et al* cf Code 1944) owing to the numerous mast cells in the parenchyma of dog s liver

During shock reactions have been shown in various organs in situ (Manwaring *et al* 1925) contraction of the uterus the in testinal tract (chiefly the colon and the rectum) and the urinary bladder

The *isolated liver perfused with antigen* in Locke s solution will not release histamine and heparin (Scroggie and Jaques 1949) but does so readily when perfused with anti gen in whole blood (Rocha e Silva)

Perhaps affording a most important clue to anaphylaxis in the dog is the observation that 2 classes of canine antibodies can play separate roles passive transfer of serum from dogs spontaneously sensitive to ragweed (see p 263) imposes anaphylactic sensitivity to ragweed extract but demonstration of ana phylaxis is blocked on injecting antiragweed serum prepared in normal dogs (Tennen baum Patterson and Pruzansky 1963) Here the anaphylactic antibody is heat labile and the second one is heat stable

Anaphylaxis in the Rabbit Systemic shock is not experienced regularly Consequently less is known about the conditions for pro ducing systemic shock in the rabbit than in either the guinea pig or the dog The concen tration of circulating antibody must be high (Jackson 1935) Passive sensitization is possible with adequately large volumes of serum (Arthus 1919) and may be demon strated without a preliminary incubation period

Upon intravenous injection of antigen rabbits that show anaphylactic shock show arrhythmic respiration then panting with temporary hyperemia in the ear followed by arteriolar contraction and blanching the rab

in skin prepared with certain guinea pig anti sera, although the sensitivity decreases with time (4) The reactions are usually to be induced far more sharply in the skin of a recipient guinea pig than in the skin of the antibody donor probably because antibody present in the latter's circulation blunts the anaphylactic type reactivity by overlaying an Arthus component

Human skin it may be noted serves for PCA type reactions for a few hours vis à vis certain rabbit immunoglobulins (see p 263) normal gamma globulins compete in fixation to skin so that highly purified rabbit antibody has been required

Organ Anaphylaxis The features of anaphylaxis encountered in the intact sensitized guinea pig are met with also in the individual organs Excised uterine tissue for example contracts on contact with specific antigen even after the organ has been perfused (Dale 1913) and so likewise strips of ileum (Schultz 1910) In the lung bronchospasm and occluding constriction may be demonstrated blood vessels constrict strips of gallbladder contract the isolated heart exhibits an increased rate of beat arrhythmia and constriction of the coronary arteries All these responses are transient the tissue soon returning to the normal state while still bathed with antigen

For detecting the existence of anaphylactic sensitivity as when antibody is not demonstrable in serum the Schultz Dale test can be carried out suspending short lengths of ileum or uterine horns from young females in a 37° C oxygenated bath with Ca^{++} but without carbonate buffer and adding antigen (Fig 1) By this means one can demonstrate readily the complete loss of anaphylactic (but not physiologic) reactivity of the tissue following one maximal response to specific antigen and through this demonstration rule out nonspecific causes of shock

A most important advance was initiated by Mongar and Schild (1957 see review of 1962) who tested in vitro the output of histamine when antigen was added to sliced but not macerated lung fragments of sensitized guinea pigs Below 15° C tissue became desensitized *without* histamine liberation Release of histamine at 37° C was found to involve a heat labile (45°) enzyme precursor (tissue complement) requiring Ca^{++} for activation The short lived enzyme system released bound histamine, probably by degranulating mast cells in the lung Sulfhydryl inhibitors blocked the release Subsequent detailed studies by Austen and Brocklehurst (1961a b c) with various enzyme inhibitors indicated that the enzyme involved resembled chymotrypsin in its specificity becoming active only after the reaction of the sensitized tissue and antigen excluded were cathepsin C carboxypeptidase trypsin, and so on Chymotrypsin itself added to lung tissue had no effect Other evidence suggested that there may be a stage in anaphylactic reaction involving the third component of complement C_3 (Chap 9)

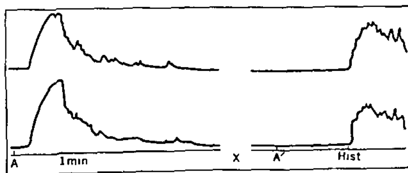

Fig 1 Schultz Dale test Two strips of uterus are tested simultaneously in the same bath *A* addition of antigen to the bath contraction occurring after a short latent period X complete replacement of bath *A'* second addition of antigen to demonstrate desensitization Hist histamine 1 20 000 000 added

Physiologic acutance to histamine				Adrenalectomy Use of *H pertussis* vaccine	Adrenalectomy	
Role of histamine	Certain	Certain	Principal constrictor	Questionable	Questionable	Certain
Role of serotonin (5 HT)	Not probable		Probable auxiliary role	Certain (Principal constrictor?)	Certain (released in intestine) (Principal constrictor?)	Not probable
SRS A	Produced in lung by Ag/Ab reaction		Produced in tissues by Ag/Ab reaction		Found by Ag/Ab reaction in peritoneal cavity	Produced in lung by Ag/Ab reaction (potent bronchoconstrictor)
Bradykinin	Present in shock (potent bronchoconstrictor)	Present in shock	Present in shock		Present in shock	Possible role
Anaphylatoxin	Can shock				Can shock	
Role of acetylcholine	Improbable	Not probable				Uncertain
G_2 α globulin (permeability factor)	Possible role					Possible role

* Data compiled by the late R L Mayer
† Datum applies to the Swiss albino mice many other strains are more resistant (cf Tokuda *et al* 1963)

TABLE 4 CHARACTERISTICS OF ANAPHYLAXIS IN CERTAIN SPECIES

	GUINEA PIG	DOG	RABBIT	MOUSE	RAT	MAN
Onset of systemic shock	3 to 6 min	10 sec (acute)	15 sec	12 to 60 min		Few seconds
Situs of acute shock	Lung bronchoconstriction	Liver gallbladder G I tract Lungs	Pulmonary arteries mechanical heart failure Liver		G I tract liver congested	Lung
Duration of sensitivity*	Many months	Long vs dog rea in	Brief	Brief	Brief	Many months‡
Fixation of antibody to tissues†	Uterus gut lung vessels gallbladder heart coronary arteries urinary bladder	Brief vs classic antibody	Strips of pulmonary artery blood vessels of lung and ear	Yes slight		Skin lung‡
Incubation period in passive transfer	Several hours	None	None	None		Several hours‡ (Prausnitz Kuestner)
Antibody in excess	Not necessary	Necessary	Necessary	Necessary		Not necessary‡
PCA	Yes (180—320 gm body weight)		Ear only	Yes		Prausnitz Kuestner reaction

* Sensitization established without use of mycobacterial adjuvants
† Reaction to A in saline after perfusion
‡ Reaginic antibody

bit becomes weak and collapses gives a few convulsive movements defecates, and dies suddenly with head retracted and eyes in exophthalmos Bronchospasm is absent but the lung is nonetheless the main organ of shock

At necropsy extreme dilatation of the right half of the heart is seen The inferior vena cava the portal vein and the liver are engorged In *1919* Coca referred the cause of death to obstruction of the pulmonary arterioles which causes right sided dilatation of the heart death being attributable to *secondary heart failure While contraction* of the abundant smooth muscle around the pulmonary arterioles was first regarded as the source of obstruction McKinnon *et al* (1957) emphasized the occurrence of obstructing intravascular amorphous micro thrombi in the pulmonary circulation that in actuality are antigen antibody precipitates as shown by the use of fluorescing antigen Clumps of leukocytes also occur even sufficient to obstruct small vessels The stickiness of leukocytes and the clumping together and clinging of these cells to the vascular endothelium may be observed in newly regenerated blood vessels of the rabbit ear when antigen enters the circulation (Abell and Schenk 1938)

In isolated organs perfused with antigen constriction of a few tissues has been shown (Table 4) but systemic anaphylaxis is attributable to antigen antibody reactions that release histamine and serotonin from the blood platelets and/or leukocytes (Katz cf Waalkes *et al* 1957) probably in close relationship to the pulmonary arteries where white cells and platelets accumulate during shock as mentioned

Liberation occurs also when antibody and antigen are added to normal rabbit blood or to buffy coat the basophile becoming degranulated meanwhile (p 266) and symptoms of shock (nonfatal) can be produced in normal rabbits by injecting antigen antibody precipitates (McKinnon *et al* 1957) In the same way adding preformed antigen antibody precipitates to normal rabbit platelets releases histamine in vitro (Barbaro 1961)

As with other animals temporary anaphylactic desensitization seems to be attained by a few subcutaneous injections of small amounts of antigen in the course of 3 or 4 hours this procedure is employed at times in resuming intravenous injections with certain antigens following periods of rest

Anaphylaxis in Rodents The actively sensitized rat and mouse highly resistant to histamine intoxication (Table 3) undergo systemic anaphylactic shock less readily than other species, and onset is slow Mast cells are injured the chief site of increased capillary permeability is the intestine where enterochromaffin cells appear to be a source of serotonin (Benditt *et al* *1963*)

Upon passive sensitization with rabbit or homologous precipitating antibodies mice and rats give evidence of anaphylaxis but no damage occurs to *their mast cells* (Mota 1963) one is again reminded of the 2 classes of antibodies described in the guinea pig by Bloch *et al* (1963) for perhaps these species too develop in active anaphylaxis a variety of antibody that fixes directly to tissues Indeed the conditions for successful passive anaphylaxis—injection of antigen and antibody closely spaced or presented as soluble antigen antibody complexes (Tokuda and Weiser 1961)—would suggest an anaphylatoxic mechanism as operative by this route Serotonin of high concentration in *rodent mast cells has been implicated* (cf Weiser 1957) both bradykinin and anaphylatoxin may be involved

The rat does not become sensitized readily unless special methods are used (Lipton Stone and Freund 1956) but rabbit guinea pig and potent rat antisera prepare rat skin for passive cutaneous anaphylaxis (Ovary 1958) Indeed Brocklehurst *et al* (1955) showed that PCA reactions were nearly normal in rats 90 per cent depleted of skin histamine by use of the compound 48/80 It is interesting to note that guinea pig 7Sγ *antibody is adequate to prepare PCA sites in* the rat even if not in the guinea pig This has been taken to mean that complement fixing antibody and perhaps anaphylatoxin are important for triggering the reactions of rats (Osler *et al* 1957 1959 Bloch *et al* 1963)

Mice can be sensitized by several injections of fluid antigen (cf Cameron 1956) but much more easily by *alum precipitated*

antigen (Solotorovsky and Winsten 1953) or other adjuvants McMaster and Kruse (1951) have employed the ear of the sensitized mouse for direct observation of vessel spasms during anaphylaxis arteriolar and venous spasm following intravenous injection of antigen is dramatic the capillaries and lymphatics remaining unaffected Mice like rats can be prepared for passive cutaneous anaphylaxis but often reversed passive cutaneous anaphylaxis is employed antibody being injected intravenously and antigen given intradermally 48 hours later

Passive sensitization is possible with potent antisera of rabbit and guinea pig and no incubation period is necessary (Burdon 1946) Several procedures enhance the anaphylactic sensitivity of the mouse adrenalectomy shortly before sensitization or pretreatment with *H pertussis* vaccine (Kind and Parfentjev 1951 review by Pittman 1957) The latter procedure renders mice more than 10 fold as sensitive to histamine as they are normally (Table 3)

Anaphylaxis in Other Animals Anaphylaxis occurs in horse calf and monkey (see p 162 ed 3) Birds may be sensitized and in particular several studies have been carried out in the pigeon the anaphylactic contractability of the isolated circular muscle of the pigeon s crop has been suggested as a laboratory tool

Systemic anaphylaxis in the monkey is not easy to secure The time of reaction to the shocking injection varied from 30 minutes to 24 hours edema and hemorrhage of the lungs and the intestinal tract and of the skin were observed when death did not occur early (see Kinsell Kopeloff *et al* 1941)

Desensitization The introduction of very small amounts of antigen beneath the skin given as a series of injections of increasing amounts over the course of a few hours without the production of symptoms serves to desensitize an animal and to render it immune to shock for some days (Besredka) In desensitization (cf Longcope 1923) it is commonly said that the available antibody is neutralized but some alteration in the reactivity of the tissue component may possibly be involved as well Practical use is still made of this procedure when sensitized animals must receive further injection (Kay 1940) it has been applied successfully to man also but it is hazardous (Friedberger and Mita 1912 Mackenzie 1921 Ratner 1943) *Eventually however with cessation of injec*tions the anaphylactic state becomes re established *there is no known technic for effecting a permanent desensitization*

Inhibition and Shock by Haptenes With the advent of artificial conjugated antigens owing to the work of Landsteiner (Chap 9) it became possible to examine by anaphylaxis the serologic specificity lent to proteins by the attachment of certain types of chemical radicals which have come to be called haptenes When guinea pigs were given sensitizing injections with such a grouping combined with one protein fatal shock could result from subsequent testing with the same grouping combined with an entirely different protein If now the haptene itself or a simple derivative of it was injected intravenously prior to the shocking conjugate a state of specific inhibition of shock was to be found akin to inhibition in vitro of a precipitating antigen antibody system that is the small molecule could compete successfully with the large protein complex for haptene-specific antibody and so delay the requisite interaction between antibody and the full antigen In some cases the effect appears to be a simple inhibition with the tissue retaining its full reactivity in others there is evidence for *specific desensitization as well*

Similarly azodyes in particular those containing 2 haptenic groupings to the molecule (made by such devices as a double coupling to resorcinol) and having probably a larger structure owing to aggregation of molecules of the *dis* azodye can cause anaphylaxis directly without use of protein carriers this matter has been pursued by Campbell and McCasland (1944) who showed further the inhibiting effect of univalent haptenes

Recently haptene amino acid conjugates (termed unifunctional haptenes) have been used to inhibit reactions given by multifunctional haptene protein conjugates with the intent to study specificity For example ε penicilloyl aminocaproate will in excess molar ratio block reactions given by penicilloyl polylysine and by penicilloyl serum albumin (see p 269)

Reversed Anaphylaxis A special instance

described as reversed anaphylaxis is presented by those animal species in whose tissues Forssman heterophil antigens are present for instance the guinea pig If an antiserum produced against some other *heterophil antigen is introduced intravenously* (such as an antiserum against sheep erythrocytes developed in the Forssman negative rabbit) the antibody reacts with the guinea pig s tissues and leads to death with pronounced anaphylactic features however the isolated guinea pig uterus is said not to respond to such antisera

The Arthus Reaction

Antigen antibody reactions that resulted in *localized* tissue damage were found by Arthus in 1903 Rabbits injected repeatedly beneath the skin with horse serum came to respond with progressively more intense reactions at the site of each succeeding injection Eventually Arthus observed hyperemia and edema that were shortly followed by hemorrhage and intense swelling progressing to deep necrosis by the following day later sloughing Study of the Arthus reaction which now is conducted by intradermal injections of antigen into well sensitized rabbits has led to additional knowledge of the effects of antigen antibody reactions in tissues

In the Arthus reaction antigen antibody complexes start forming promptly shortly leading to precipitation in the vessel walls Vascular damage and thrombus formation soon occur but the final consequences—*necrosis of the arteriolar vessel wall hemor*rhage fibrinoid degeneration and edema when the antibody concentration is sufficiently high—require several hours to a day or more

The earlier stages have been studied by Gerlach (1923) Stetson (1951) and Gell and Hinde (1954) Stetson noted pronounced but transient leukopenia within 15 minutes the cells and the platelets being sequestered by adhesion to the endothelium of small vessels aggregates of leukocytes and platelets appeared at the site of injection and formed thrombi Along with vasodilatation and injury to the vascular endothelium swelling of connective tissue fibrils and massive edema occurred locally With the continued increase in numbers of leukocytes at the local site over a period of several hours there was detected an abnormal accumulation of lactic acid owing to aerobic glycolysis by the exudate leukocytes

The acute phase appears to be over by 8 hours (Gell and Hinde, 1954 Cochrane *et al* 1959) Many polymorphonuclear leukocytes are then degenerate still others of them ingest and begin to degrade the antigen antibody precipitate At 8 hours a circumferential mononuclear cell reaction is present In the zone of the mononuclear cells, immature plasma cells and eosinophils are seen by the 4th day and thereafter progression to plasma cells proceeds apace Although several aspects of this mononuclear contribution are seen also in tuberculin reactions of the delayed type the final appearance of plasma cells is confined to the Arthus reaction

Polymorphonuclear leukocytes are essential for inflammatory necrotizing reactions removal of the leukocytes by prior treatment with nitrogen mustard inhibits the Arthus reaction but the Arthus reaction starts up on the eventual return of these cells since the antigen antibody precipitates have not been removed (Stetson 1951)

In relatively avascular cornea slowly developing but marked inflammatory changes can be demonstrated in sensitized rabbits by intracorneal injection of protein (Germuth *et al* 1962) in such sub Arthus' reactions antibody diffuses into the cornea from injured vessels at the limbus producing a local formation of antigen antibody precipitate (cf Movat *et al* 1963) Collagen fibers it has been said become swollen and fragmented but recent studies by Movat *et al* (1963) have not confirmed such alterations The reaction occurs even in animals largely depleted of polymorphonuclear leukocytes by nitrogen mustard treatment

The fixed tissue cells are not themselves sensitive but owe their capacity to react to environmental cellular elements and plasma factors for cells of the sensitized rabbit survive normally in tissue culture when antigen is added

In Arthus reactions ideal conditions apparently exist for antigen antibody complexes to degranulate polymorphonuclear leukocytes intracellular enzymes being freed in

high local concentration along the walls of vessels Platelets give up histamine and serotonin (Table 2) and mast cells in the local site become degranulated The activation of enzymes may bring plasma kinins into play

One newly described factor not discussed above may come into play in tissue reactions that are prolonged over several hours Schayer (1961 1963) has pointed out that histidine decarboxylase is an inducible enzyme contained in the endothelial cells its amount increasing markedly under stress within short periods of time Consequently there is available in an animal not only its preformed histamine but an induced synthesis of new histamine The total amount would not be large but its synthesis for some time in injured endothelium should aggravate vessel permeability increase diapedesis of cells and tend to prolong the local reaction

The intensity of the Arthus reaction varies with the concentration of immune globulin in the serum 120 to 160 mcg antibody nitrogen/ml being required for deep necrosis and slough (Culbertson 1935) Passive transfer of sufficient amounts of immune serum intraperitoneally or intravenously determines typical Arthus reactions upon intradermal injection of antigen and the binding with antigen is found to be maximal within 15 minutes (Benacerraf and Kabat 1950)

A more delicate measurement is reversed passive transfer in which antibody is injected into the dermis and antigen is supplied locally or intravenously Because rabbit antibody does not fix in rabbit skin antigen usually is given intravenously prior to the intradermal injection of antibody The amount of immune globulin needed for reversed passive transfer has been determined as 225 mcg antibody nitrogen for maximal and 24 mcg for minimal reactions (Fischel and Kabat see Kabat and Mayer 1961)

A clear differentiation between anaphylactic and Arthus type sensitivities of the guinea pig was made in 1950 (Benacerraf and Kabat) antibody made both in rabbit and in guinea pig being used In recent studies of Benacerraf and his group (1963) in which guinea pig antibodies are separated into $7S\gamma_1$ and $7S\gamma$ classes it turns out that the 2 varieties of antibody play rather different roles anaphylactic sensitivity is determined by the $7S\gamma_1$ whereas Arthus type reactions are induced—differently—by both The $7S\gamma$ antibody which fixes complement gives rise in reversed passive Arthus tests to hemorrhagic necrosis and $7S\gamma_1$ contributes markedly to the edema (Bloch *et al* 1963) It will be useful to cite the previously described distinguishing features applicable to the use of rabbit antibody as well (1) There is no need of a latent or incubation period before demonstrating passive Arthus reactivity whereas there can be such a requirement for passive anaphylactic sensitization with the lapse of some hours both states coexist (2) The amount of antibody required upon intravenous injection for Arthus type reactivity to be established is considerably greater than that for fatal anaphylactic sensitization (3) Nonprecipitating or univalent rabbit antibody leads only to a low grade Arthus reactivity although it is as effective as precipitating antibody in transferring anaphylactic sensitization (4) Obversely Arthus type sensitivity of moderate intensity is established by injecting antibody of the horse (one reacting with pneumococcal carbohydrate) which is not able to induce anaphylactic sensitivity

The amount of antibody required for reversed passive Arthus reactions in the guinea pig has been measured about 200 mcg antibody nitrogen produces maximal reactions and 10 mcg minimal reactions about the same values as those found in the rabbit (Benacerraf and Kabat 1950) Rabbit antiovalbumin and guinea pig anti ovalbumin were found to be quantitatively equivalent but rabbit nonprecipitating or univalent antibody was markedly inferior

Arthus type reactivity occurs also in monkey (Kopeloff and Kopeloff 1939) horse (Gerlach 1922) and man It is not induced readily in the rat and the mouse except in the lip owing to the number of mast cells found there (Freund and Stone 1956)

A final example apparently the creation of a local Arthus reaction by causing polymorphonuclear leukocytes to concentrate in an area of the skin and there to be affected by antigen antibody complexes forming and

circulating in the bloodstream is provided by experiments of Opie (1936) and Klinge (1933) They showed that localized inflammatory responses may be caused in sensitized rabbits by irritating the skin by xylol or heating or chilling antigen being injected into the circulation

Upon injecting soluble antigen antibody complexes Ishizaka and Campbell (1958) had noted increased vascular permeability in the skin and Cochrane and Weigle (1958) had found Arthus like responses With the thought that this result might be referable solely to gamma globulin molecules held closely oriented in the soluble complex Ishizaka *et al* (1959 1961) aggregated *normal* gamma globulin by heating or by cross coupling with bis diazobenzidine such *aggregates if formed of rabbit or human* gamma globulins indeed gave Arthus type hemorrhagic responses in guinea pig skin and fixed complement to the same degree as soluble antigen antibody complexes Accordingly tissue damage can result from interaction of normal gamma globulin molecules serum complement playing a necessary role Ishizaka (1963) recently has reviewed the role of gamma globulin in hypersensitivity reactions Gamma globulin complexes interacting with serum can activate esterase (from complement fraction C_1) fibrinolysin anaphylatoxin and bradykinin

Localized Tissue Damage

Many workers have injected antigen into sensitized animals in order to explore the pathologic consequences In most experiments of this type the amounts of antigen introduced have been large artificially so in terms of duplicating exposures to antigen that might occur in disease but indeed sites *other than the skin* of sensitized rabbits develop an inflammatory response when antigen is injected locally (e g stomach submucosa testicle kidney and other organs ligatured blood vessels *knee joints pericardium and* myocardium) Thus Klinge (1933) injected antigen into knee joints of sensitized rabbits and produced intense inflammation extending to the adjacent soft tissue with necrosis and collagenous degeneration and repeated injections led to severe destructive and deforming arthritis

Some experiments have approached the problem of disease in more promising fashion Unilateral glomerulonephritis has appeared in sensitized rabbits following the injection of bacterial cells directly into the renal artery (Lukens and Longcope 1931), evidently because of a local retention of bacillary antigen in high concentration

In an attempt to study the genesis of human rheumatic fever Murphy and Swift (1949, 1950) induced successive infections with different serologic types of group A streptococci in a proportion of rabbits subjected to a series of intracutaneous infections over a long period of time cardiac lesions were found that resembled closely those of human rheumatic fever including Aschoff bodies (cf Murphy, 1963) Streptococci *were chosen because of the long suspected* association between rheumatic fever and preceding streptococcal infection Genetic factors appeared to determine the proportion of the rabbits thus affected (In some instances however comparable lesions were found to be induced by large amounts of foreign serum)

Most interesting results have been found in newer studies of so-called Masugi nephritis Here onset of experimental glomerulonephritis is induced by administering low titer specific antikidney antibodies made in other species The foreign gamma globulin attaches to the renal tissue for which it possesses specific affinity constituting there a local concentration of foreign antigenic protein (cf Pressman Korngold and Heymann 1953 Hammer and Dixon 1963) Nearly immediate onset of kidney damage follows the injection of first quality immune sera (cf Hasson Bevans and Seegal 1957 Seegal and Bevans 1957) but such sera in diluted form or sera possessing lower concentrations of antibody require a latent period of 4 to 12 days for the production of host antibody against the foreign gamma *globulin Once initiated the acute* glomerulonephritis can prove to be fatal within a few days or it can undergo remission for several months to be followed by chronic nephritis that persists for months or years The reason for persisting nephritis appears to be deposition of antigen host antibody and components of complement on the base

FIG 2 Section through submucosa of stomach of rabbit subjected to allergic insult showing marked necrosis of medium sized arteries An oblique section of an artery has been exposed revealing 2 segments of its lumen Marked localized damage is evident There is slight infiltration of polymorphonuclear leukocytes in and about the necrotic arterioles Hematoxylin and eosin stain × 75 The histologic finding is typical this particular animal was prepared passively by the slow infusion of antibody after injection of antigen (Germuth F G Jr and Pollack A D 1958 Bull Johns Hopkins Hosp 5 245 Photograph from Dr F G Germuth Jr)

ment membranes of the glomeruli (Fig 4)

Another technic has been to inject into the bloodstream of normal animals very large doses of antigen (0 25 to 1 Gm /Kg protein or 10 ml /Kg foreign serum) the protein being intended both to sensitize and by its persistence in the tissues to provide residual antigen for reaction with newly formed antibodies It will be recognized that this procedure is based on but exaggerates the one that used to lead quite regularly to the development of serum sickness in man when antiserum produced in a foreign species was injected for prophylaxis (antitetanus antidiphtheria serums)

Intensive studies of the pathology produced in normal rabbits following administration of large initial intravenous doses of horse serum were carried out by Rich *et al* (1943 1947) whose studies of fulminating serum disease in man pointed convincingly

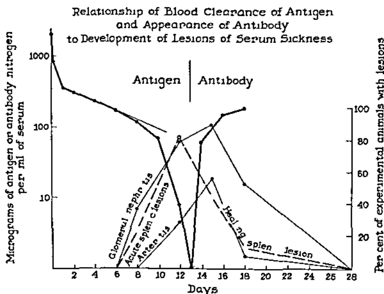

FIG 3 A comparative histologic and immunologic study in rabbits of induced hypersensitivity of the serum sickness type (Germuth F G Jr 1953 J Exp Med *97* 272)

circulating in the bloodstream is provided by experiments of Opie (1936) and Klinge (1933) They showed that localized inflammatory responses may be caused in sensitized rabbits by irritating the skin by xylol or heating or chilling antigen being injected into the circulation

Upon injecting soluble antigen antibody complexes Ishizaka and Campbell (1958) had noted increased vascular permeability in the skin and Cochrane and Weigle (1958) had found Arthus like responses With the thought that this result might be referable solely to gamma globulin molecules held closely oriented in the soluble complex Ishizaka *et al* (1959, 1961) aggregated *normal* gamma globulin by heating or by cross coupling with bis diazobenzidine such aggregates if formed of rabbit or human gamma globulins indeed gave Arthus type hemorrhagic responses in guinea pig skin and fixed complement, to the same degree as soluble antigen antibody complexes Accordingly tissue damage can result from interaction of normal gamma globulin molecules serum complement playing a necessary role Ishizaka (1963) recently has reviewed the role of gamma globulin in hypersensitivity reactions Gamma globulin complexes interacting with serum can activate esterase (from complement fraction C 1) fibrinolysin anaphylatoxin and bradykinin

Localized Tissue Damage

Many workers have injected antigen into sensitized animals in order to explore the pathologic consequences In most experiments of this type the amounts of antigen introduced have been large artificially so in terms of duplicating exposures to antigen that might occur in disease but indeed sites other than the skin of sensitized rabbits develop an inflammatory response when antigen is injected locally (e g stomach submucosa testicle kidney and other organs ligatured blood vessels knee joints pericardium and myocardium) Thus Klinge (1933) injected antigen into knee joints of sensitized rabbits and produced intense inflammation extending to the adjacent soft tissue with necrosis and collagenous degeneration and repeated injections led to severe destructive and deforming arthritis

Some experiments have approached the problem of disease in more promising fashion Unilateral glomerulonephritis has appeared in sensitized rabbits following the injection of bacterial cells directly into the renal artery (Lukens and Longcope 1931) evidently because of a local retention of bacillary antigen in high concentration

In an attempt to study the genesis of human rheumatic fever Murphy and Swift (1949, 1950) induced successive infections with different serologic types of group A streptococci in a proportion of rabbits subjected to a series of intracutaneous infections over a long period of time cardiac lesions were found that resembled closely those of human rheumatic fever including Aschoff bodies (cf Murphy 1963) Streptococci were chosen because of the long suspected association between rheumatic fever and preceding streptococcal infection Genetic factors appeared to determine the proportion of the rabbits thus affected (In some instances however comparable lesions were found to be induced by large amounts of foreign serum)

Most interesting results have been found in newer studies of so called 'Masugi nephritis Here onset of experimental glomerulonephritis is induced by administering low titer, specific antikidney antibodies made in other species The foreign gamma globulin attaches to the renal tissue for which it possesses specific affinity constituting there a local concentration of foreign antigenic protein (cf Pressman Korngold and Heymann 1953 Hammer and Dixon 1963) Nearly immediate onset of kidney damage follows the injection of first quality immune sera (cf Hasson Bevans and Seegal 1957 Seegal and Bevans 1957) but such sera in diluted form or sera possessing lower concentrations of antibody require a latent period of 4 to 12 days for the production of host antibody against the foreign gamma globulin Once initiated the acute glomerulonephritis can prove to be fatal within a few days or it can undergo remission for several months to be followed by chronic nephritis that persists for months or years The reason for persisting nephritis appears to be deposition of antigen host antibody and components of complement on the base

3) It is evident that the acute lesions—glomerulonephritis arteritis and reversible granulomatous lesions in the spleen and the lymph nodes—occurred during very early antibody synthesis when antibody could be determined only by change in the rate of clearance of antigen from the bloodstream and by consumption of serum complement (Dixon *et al* 1961) (The minimal amount of antibody required to produce this degree of immune clearance was estimated as 2 5 to 4 0 mg of antibody nitrogen in the entire circulation) Next it will be noted that upon disappearance of free antigen and the finding of circulating antibody the various lesions resolved shortly It is evident that the lesions occurred while antigen antibody complexes formed in antigen excess were present and indeed these complexes can be found at the site of damage by fluorescent antibody technics The transient nature of even acute lesions after one injection of antigen and their occurrence only in certain rabbits—the better antibody producers—are evidence of how baffling the problem had been prior to this time

Dixon Feldman and Vasquez (1961) extended this work by giving smaller repeated doses of antigen instead of 1 large injection to a large number of rabbits during many months Here the rabbits suffering from lesions were *not* the better antibody producers (for such animals quickly eliminated each dose of antigen) but the poor antibody producers able to synthesize just enough antibody to form antigen antibody complexes in antigen excess and to retain these for a time in the tissues An example is shown in Figure 4 A and B The lumpy dense deposits along the outer aspect of the basement membrane consist of antigen antibody complement complexes Antigen is localized by staining either with fluorescent antibody or with ferritin tagged antibody (Andreas *et al* 1963) One can draw the conclusion that repeated allergic insults with antigen in persons unable to respond well to the antigenic stimulus may constitute a cause of chronic allergic disease in the tissues

Another example of allergic damage caused apparently by a high local concentration of antigen antibody complexes was provided in artificial manner by Kopeloff and Kopeloff (1949) These workers by introducing antigen into the foot of the guinea pig 3 or 4 days before the onset of sensitivity—established principally from a distant repository of the same antigen in a water in-oil emulsion—produced a most striking inflammatory reaction leading to a chronic arthritic deformity of the foot

Immediate Type Allergies of Man

From the studies made on animals the occurrence of the early type of reaction clearly coincides with the presence of antibodies capable of sensitizing normal individuals the apparent exception being a persisting sensitivity in some animals principally the guinea pig for many months after the antibody has become undetectable in the serum this state is probably due to continued synthesis of antibody in very low concentration followed by fixation to tissues as the transient sensitivity of litters born to female guinea pigs suggests

In man there occur Arthus type reactions anaphylactic shock and localized tissue damage such as glomerulonephritis all related to immunoglobulins We must make it clear at the outset that questions regarding the nature of the antibodies concerned and the subjects capable of producing them are not to be resolved simply So called classic antibodies are produced in man—agglutinins to invading microorganisms and transfused incompatible erythrocytes precipitins to foreign proteins pneumococcal polysaccharides dextrans and so on and univalent antibodies as seen especially in the Rh blood typing system Several other types are known chiefly by studies in man—allergic reagins blocking antibodies and hemagglutinins to pollen extracts

As will be mentioned below the capacity to synthesize reaginic antibodies is supposedly inherited only a small proportion (5 to 15%) of individuals (termed atopic from *atopy* strange disease) exhibiting allergic diseases of the acute type Very many individuals synthesize reaginic antibody in response to horse serum and special materials such as Ascaris extract but the synthesis is apparently transient in contrast with that of atopic individuals

Episodes of acute anaphylactic shock in

to sensitization as the cause of periarteritis nodosa

Rabbits given horse serum (10 ml /Kg) were sacrificed between 1 and 7 days after the last injection and various types of pathology were found—acute necrotizing arteritis glomerulonephritis of several degrees of severity granulomatous lesions in the spleen and the lymph nodes endocarditis and subendothelial cellular infiltrations (Rich and Gregory 1943) The principle being once established subsequent workers have injected normal rabbits with preformed antigen antibody complexes or have injected antigen intravenously and then infused antibody slowly A typical instance of pathology produced in this way is shown in Figure 2

Most interesting principles emerged when Germuth (1953 Germuth *et al* 1957) and later Dixon *et al* (1961) studied the time at which lesions appeared in relation to antibody synthesis After a single injection of bovine albumin lesions appeared only in those animals that were best able to respond to antigen by early antibody production (Fig

3) It is evident that the acute lesions—glomerulonephritis arteritis and reversible granulomatous lesions in the spleen and the lymph nodes—occurred during very early antibody synthesis when antibody could be determined only by change in the rate of clearance of antigen from the bloodstream and by consumption of serum complement (Dixon *et al* 1961) (The minimal amount of antibody required to produce this degree of immune clearance was estimated as 2 5 to 4 0 mg of antibody nitrogen in the entire circulation) Next it will be noted that upon disappearance of free antigen and the finding of circulating antibody the various lesions resolved shortly It is evident that the lesions occurred while antigen antibody complexes formed in antigen-excess were present and indeed these complexes can be found at the site of damage by fluorescent antibody technics The transient nature of even acute lesions after one injection of antigen and their occurrence only in certain rabbits—the better antibody producers—are evidence of how baffling the problem had been prior to this time

As will be mentioned below the capacity to synthesize reaginic antibodies is supposedly inherited only a small proportion (5 to 15%) of individuals (termed atopic from *atopy* strange disease) exhibiting allergic diseases of the acute type Very many individuals synthesize reaginic antibody in response to horse serum and special materials such as Ascaris extract but the synthesis is apparently transient in contrast with that of atopic individuals

Episodes of acute anaphylactic shock in

man appear to be referable to the human reagin which binds to tissues rather than to other antibodies but it is possible that in stances of delayed shock can involve other types of antibodies

For example Werne and Garrow (1946) reported delayed shock regarded as an in stance of anaphylaxis and certainly related to antibody production Following 2 injections of a prophylactic preparation of alum precipitated diphtheria toxoid and pertussis antigen identical twins died in delayed shock 16 and 24 hours, respectively after the 2nd *injection A role played by hereditary factors* seems to be obvious Both children showed histopathologic evidence of acute vascular injury and edema constricted ar teries and tissue eosinophilia (The prepara tion used for the injections it may be added was shown to produce no untoward reac tion in many other children)

In linking immediate type allergies of man to participation of antibodies it is necessary to point out that antibodies have not been surely demonstrated in for example eczema urticaria (hives) and *angioneurotic edema* Likewise some instances of food allergy can occur without evidence of circulating anti body or cutaneous reactivity to the offend ing foodstuff for these Coca introduced the term familial nonreaginic food allergy Modern developments in biochemistry and in immunology should allow resolution of *these areas for a role of antibodies is most* probable

To connote sites of predilection for allergic reactions seen in various individuals allergists have introduced the term shock organ —the bronchial mucous membrane (asthma) the mucous membrane of the eyes and the upper respiratory tract (hay fever allergic coryza or rhinitis) the endothelium of the superficial vessels in the upper cutis (urti caria wheal reacting allergies) the gastro intestinal tract (forms of food allergy) and the like The implication that antibodies are distributed unequally among the various tis sues suggests a need for critical experimenta tion To some extent the concept of a par ticular shock organ will be an artificiality for the observed reaction may reflect the usual route of contact with the allergen vis a vis the intensity of the sensitivity rather than solely the existence of loci with exaggerated sensitivity For example a person who suffers only from hay fever under natural conditions of exposure will sometimes exhibit instead an attack of asthma or a generalized urticaria when his allergen is *injected for prophylactic* purposes

Arthus Reactions in Man Lesions of the Arthus type can occur in man but are seen only under special circumstances

An excellent example occurred in 1909 (Lucas and Gay) when a decision was reached to sustain immunity against diph *theria in institutionalized children by giving* subcutaneous injections of antitoxic horse serum at 3 week intervals Unwittingly, in view of then current knowledge it was found that between the 2nd and the 6th injections there appeared in addition to scattered cases of generalized urticaria the characteristic local changes—edema tenderness erythema and marked persistent induration or eventual necrosis

Reactions of Arthus type were seen in re cent times in some individuals who received a *single deep intramuscular injection* of peni cillin in a beeswax and oil vehicle Appar ently, antibodies arose to some component of the injection mass and reacted with the antigen still partly held in situ

Therapeutic injections of immune horse serum given to severely ill, sensitive patients have at times produced extraordinarily ex *tensive reactions and sometimes have* even showed black dry eschars over large areas (Gatewood and Baldridge 1927 Tumpeer *et al* 1931) Extensive slough of the skin and the subcutaneous tissue has been noted (Kohn McCabe and Brem 1938) Whether or not there is some auxiliary role attribut *able to concomitant bacterial disease is un* known—for example participation of the Sanarelli Shwartzman phenomenon (p 293) Passive transfer of local serum reactivity in man has been reported by Kojis (1942)

Serum Disease * After the discovery and the clinical application of diphtheria anti toxin *the illness known as serum sickness* came to attention Patients treated by thera peutic injections of a single dose of antitoxic

* The monograph by von Pirquet and Schick (1905) is comprehensive see Longcope and Wink enwerder (1941) and Ratner (1943)

horse serum showed within 7 to 12 days—closely similar to the time required for the development of the anaphylactic state in the guinea pig—widespread urticarial or erythematous eruptions with intense itching a generalized swelling of lymph nodes and often edema of the eyelids the face and the ankles In severe cases arthralgia and fever followed the eruption

The disease appears as a consequence of the interaction between specific antibodies newly formed and remaining traces of foreign proteins The disease may be transient (the usual period is slightly over 2 days) or it may last up to 2 weeks With use of crude horse serum there were usually several spontaneous recurrences of the eruption attributable to the fact that antibody formation is established at different times to the various serum proteins Hawn and Janeway (1947) showed for example that serum sickness following injection of isolated beef gamma globulin occurred in 7 days and in 14 days when beef albumin was employed alone Similarly in rabbits the times for beef gamma globulin and beef albumin to induce pathologic changes after single injections followed the pattern seen here for human serum disease owing to the differential rate of catabolism of these proteins gamma globulin produced chiefly kidney and nonarterial heart lesions and albumin caused arterial lesions (Hawn and Janeway 1947 Heptinstall and Germuth 1957)

The incidence of serum sickness today is reduced because of a lessened use of sera of animal origin and because of chemical modifications to which some immune globulins can be submitted (e g partial cleavage with pepsin as in the *Parventjev process cf Rose et al* 1962) Antibody preparations to tetanus toxin were long used as a prophylaxis following wounds but the present trend is to immunize in the early years with tetanus toxoid and also with diphtheria toxoid Nevertheless it was estimated that 136 000 doses of tetanus antitoxin were administered in Canada in 1 year (Toogood 1960) with 7 900 allergic reactions

In serum disease antibodies have been found in patients sera, giving precipitation in vitro with horse serum anaphylactic sensitization in the guinea pig and tanned cell hemagglutination reactions versus horse serum (Longcope and Rackemann 1918 Tuft and Ramsdell 1929 Arbesman *et al* 1962) and like findings appeared in certain allergies to common foods (*Schloss 1912*) These antibodies being precisely those that were to be expected in view of the antigenic stimulus the disease came to be regarded as either an anaphylactic or an Arthus type allergy as would be consonant with the involvements of joints and lymph nodes (cf Table 1) At the same time skin sensitizing antibodies having the characteristics of reagins often are present (de Besche 1923) and perhaps are responsible for the urticaria and the itching Arbesman *et al* (1962) found that reagins arose with the onset of clinical symptoms preceding the rise of antibodies that are measured by hemagglutination and falling while the antibodies demonstrable by tanned cell hemagglutination still persisted (Similarly transient display of wheal and flare reactions but persistence of hemagglutinins was found by Fisher and Connell (1963) upon actively sensitizing a normal nonatopic volunteer with ragweed extract) Clearly both skin sensitizing reagins and classic antibodies occur together In this regard it may be mentioned that the antibodies present in serum sickness can be demonstrated advantageously by reversing the sequence of injections used in the Prausnitz Kuestner technic probably because antibodies other than reaginic skin sensitizing antibody can participate (Voss 1938 Wright and Hopkins 1941 Karelitz and Glorig 1943)

In predicting which patients would develop serum sickness Arbesman *et al* (1962) *stated that the greatest correlation* was observed with patients having pre injection titers against horse serum-coated tanned erythrocytes greater than 1 200 by their method

Reinjection at a time when the sensitivity is sufficiently high may cause local immediate reactions within 15 minutes to an hour and also general immediate reactions occurring within some minutes to 12 hours generalized immediate reactions often are severe and occasionally may prove to be fatal Further mention will be made below

If the antibody producing mechanism has

been established by some previous but not too recent injection a new administration of the same foreign protein will bring on the original train of events after a shorter interval 3 to 5 days (accelerated reaction) paralleling the recall phenomenon observed when animals are restimulated with antigen after a rest period

In recent years clinical manifestations closely resembling serum disease have been seen as a consequence of drug therapy for instance with the sulfonamides, the arsphenamines penicillin and others (Longcope, 1943 cf Carr 1954) A formation of derivative antigens in vivo between tissue component and chemical probably explains the sensitizing effect and could account for the frequent failure to find antibody or to reveal skin sensitivity by use of the chemicals themselves The pattern of serum disease is manifest in the occurrence of fever skin eruptions (erythema urticaria or purpura) and lymphadenopathy and as an aftermath of sensitization both accelerated and immediate types of response are to be encountered upon readministration of the drug

Anaphylaxis in Man Reactions that were judged to be anaphylactic in character were noted in the older experiences with foreign serum as during the course of spaced intrathecal injections of antimeningococcal horse serum employed therapeutically for meningitis Most of the fatal and grave incidents encountered in administering horse serum occurred in people having a pre-existing clinical *sensitivity to horse dander that is horse* asthmatics (Ratner and Gruehl 1929) and again it is the reaginic antibody and atopic individuals that are implicated Most prone to systemic accidents were those who gave immediate flare and wheal reactions in skin testing (This statement holds also for persons sensitive to insect stings e g bees wasps)

An ostensible instance of reversed anaphylaxis not dependent on reagins was seen in uterine contractions following the administration of specific horse antipneumococcal sera to women ill with lobar pneumonia and consequently possessing pneumococcal polysaccharide

In recent years fatal reactions to penicillin (p 269) have been noted as well as to bee venom foreign protein and pollen extracts all of these being related to the allergic state and probably to a reaginic mechanism (cf James and Austen 1964)

Longcope and Winkenwerder (1941) reviewed the severe reactions occurring after administration of horse serum—collapse fall of blood pressure tachycardia dyspnea of the asthmatic type suffusion of the face urticaria with giant wheals and sometimes marked edema of the entire body in fatal cases death would occur within a few minutes or as late as 24 hours Postmortem examination was apt to reveal distended lungs splanchnic congestion and at times engorgement of the liver

Quite recently James and Austen (1964) examined 6 instances of fatal anaphylaxis in which death ensued within 16 minutes to 2 hours Hyperinflation of the lungs was encountered in the 5 cases presenting respiratory symptoms Both grossly and microscopically there was obstructing edema of the hypopharynx epiglottis and larynx in 4 patients, and microscopically there was acute emphysema in all 5

One lesson remains to us whenever it is deemed advisable to inject a foreign protein the possibility of pre existing sensitivity must be kept in mind Testing for immediate type sensitivity is generally practiced by cautious intracutaneous injection and conjunctival instillation of *dilute material* waiting up to 2 hours for evidence of a reaction prior to therapeutic administration of antisera of *animal origin* As Longcope emphasized (1943) there should be employed in addition a preliminary intravenous test with 0 1 ml or less of the material untoward reactions may occur in the absence of positive cutaneous and conjunctival tests as is comprehensible in view of the several varieties of antibody mentioned above

Allergic Coryza (Hay Fever) The prompt response that occurs in patients who encounter pollen to which they are sensitive and their physiologic reactions when pollen extract is injected in too high a concentration constitute a prime example of anaphylaxis in man (The other chief example is afforded by insect stings which will not be treated here) The parallelism between human and guinea pig anaphylaxis is shown in Table

TABLE 5 COMPARISON OF HUMAN ANTIBODIES ENCOUNTERED IN ALLERGIC CORYZA AND ASTHMA

	REAGIN	CLASSIC 7S ANTIBODY
Heredity implicated	Yes (Atopics)	No
Antigenic stimulus	Natural exposure (spontaneous)	Via injection (traces by natural exposure)
Protein type	β_A globulin also others (?)	γ globulins
Ultracentrifugation $S_{w\,0}$	8 to 11S	7S
Heating at 60 C	Labile	Stable
Reaction in vitro with antigen	Allergen bound to immune precipitates of reagins (??)	Precipitation shown by special methods in patients serum
Passive sensitization of skin	Fixes to skin mucous membranes of nose eye intestine	Leaves skin readily
Prausnitz Kuestner test	Yes	No
Placental passage	No	Yes

4 Because of the danger of anaphylaxis associated with the injection of specific allergens dilute solutions are used and epinephrine is kept ready the latter both relaxes smooth muscle and contracts some of the peripheral vessels

The antibody responsible is the human reagin * (1) It fixes to normal skin upon passive intradermal transfer and gives flare and wheal reactions when the corresponding allergen is injected intradermally into the same site (Prausnitz Kuestner 1921 the P K technic) or is absorbed following injection of larger amounts into remote tissues (Lippard and Schmidt 1937) Injected sites can give some measure of response when tested initially as long as 45 days later (2) The antibody differs from classic antibodies (Table 5) in several respects it is heat labile (56° to 60 C for 1 to several hours) it fails to show visible reaction in vitro with the corresponding allergen it is associated with β_A globulins and perhaps with other serum globulins but not with the classic gamma globulins it is dissociated by mercapto-ethanol (Leddy *et al* 1962) It is absent in children born to allergic mothers and it is not able to sensitize guinea pigs anaphylactically even though other human antibodies can prepare sites for passive cutaneous anaphylaxis in guinea pigs

Its prototype has been found in a few dogs suffering spontaneously from allergic coryza (Wittich 1941 Patterson 1960) in certain cows (Reddin 1948) in rabbits (Sherman *et al* 1939 cf Vaughan and Kabat 1953 Aladjem *et al* 1957) and probably in guinea pigs (Caulfeild Brown and Waters 1937) as judged by heat lability The rabbit and the guinea pig antibodies are assigned to the class of reagins principally because of demonstrated fixation in human skin Intensive studies of dogs spontaneously allergic to ragweed are presently being conducted Transfer of dog reaginic serum imposes anaphylactic sensitivity as well as cutaneous sensitivity and asthmatic attacks occur by inhalation of the allergen (Patterson and Sparks 1962 Tennenbaum *et al* 1963)

It should be noted that isolated specific rabbit immunoglobulins (prepared to dinitrophenylated proteins and to penicilloyl bovine gamma globulin) will serve to sensi

* Reagins or less precisely skin sensitizing antibodies are not to be confused with Wassermann reagin which for long has been a designation for the syphilitic antibody

tize and to produce wheal and flare reactions in human skin the nonreaginic antibody having a half life of only 10 hours (Farah Kern and Eisen 1960 Parker *et al* 1962)

The flare and wheal reaction appearing in sensitive persons by scratch testing through drops of allergenic extract or more exactly by injecting graded doses intradermally, consists of 3 developmental phases duplicating those seen upon injecting histamine into human skin (the triple response described by Sir Thomas Lewis) (1) local capillary vasodilatation producing an initial erythema (2) a local axon reflex causing widespread *arteriolar dilatation and producing a flush* or flare spreading gradually from the center (3) an increase of permeability in the integrity of minute blood vessels allowing very rapid passage of fluid with development of a wheal (a sharply circumscribed and elevated blanched central area sometimes showing pseudopodial extensions) The entire area involved may extend from 3 to 10 or more centimeters in diameter with a wheal of 1 to 3 centimeters The reaction occurs within 5 to 30 minutes and usually begins to fade *within a further 15 to 60 minutes after which* the skin nearly regains its normal appearance

Not every person synthesizes reagin under conditions of natural exposure those who do so *being classed as atopics It is widely be*lieved that the synthesis of reagins is an inherited capacity (Cooke and Vander Veer 1916 Spain and Cooke 1924) indeed only between 5 and 15 per cent of the population suffer from atopic diseases and it seems that hay fever (with asthma) runs in families The inheritable property is a susceptibility for sensitization only since the allergens concerned and the type of clinical manifestations vary among sibs and between children and their parents

The development of reagins or the reaginic type of skin reactivity in a sample of the population has been observed several times under conditions of natural exposure e g, to dead sewage flies (Psychoda) (Ordman 1946) and to castor bean pomace (Figley *et al* 1928 1950) The small proportion of reactors among those exposed is at least consonant with the idea of inherited susceptibility At the other extreme is the formation of the reagin type of antibody by many persons upon adequate artificial immunization with selected materials namely, extracts of Ascaris (Rackemann and Stevens 1927 Davidson Baron and Walzer 1947) and of Trichina (Baron and Brunner 1942) and horse serum (p 261) Apparently in an intermediate position between these 2 groups stands the relatively high proportion—at least 40 per cent—of persons who develop flare and wheal reactions to an impurity contained in diphtheria toxoid in consequence of a single booster dose of partially purified toxoid (Kuhns and Pappenheimer 1952 Relyveld Henocq and Raynaud 1961) The problem is difficult e g among bakers in Denmark *developing clinical sensitivity to flour no evi*dent familial susceptibility could be established (Schwartz 1952)

THE PRAUSNITZ KUESTNER TEST The passive sensitization of normal volunteers with patient s serum remains the only sure identification of the human reagin In sensitizing passively one sees the same relationship as in establishing passive anaphylaxis in the guinea pig a given amount of reaginic serum will produce markedly greater sensitivity if a latent period of 1 day is observed but *it is possible at the cost of working* with submaximal reactions to obtain immediate reactions by injecting allergen and reagin together when the latter is sufficiently concentrated *A more compelling reason to observe* a waiting period is to avoid misinterpretation since immediate whealing can be produced in human skin by the toxic effects of certain sera and by mechanical trauma * As with all transfers of human serum the danger of serum hepatitis must be weighed

Human reagins fix in the tissues of monkeys Walzer having used rhesus monkeys for passive sensitization of the stomach submucosa and so on (see Walzer 1941) Rather recently it has been shown that the *Macaca irus* monkey can give useful passive sensitization of the skin (Layton Lee and DeEds 1961) and some workers are using such animals as substitutes for human volunteers It is necessary to elicit locally prepared sites by *intravenous* challenge with Evans

* Immediate whealing is produced in normal individuals upon injection of aggregated human gamma globulin formed by heat or coupling via bis-diazotized benzidine (Ishizaka *et al* 1961) The activity of such aggregates appears to be related to their interesting property of binding serum complement

Blue and allergen and monkeys can be reused several times at intervals of 2 weeks before they become refractory to human reagin An intravenous injection of as little as 3 ml of human reaginic serum prepares the animals for general cutaneous reactions and for ex hibiting typical asthma by inhalation of the corresponding pollen

There is a high correlation between reagins and clinical disease in wheal reacting aller gies but failure to detect reagins by passive transfer (P K) in the circulation does not mean the absence of disease upon exposure owing perhaps to continued synthesis in trace amounts and tissue fixation of reagins

One unresolved problem is that reagins have been found in individuals who show no corresponding clinical allergy (Grow and Herman 1936) judgment having been made on the basis of history (natural exposures) and not under experimental conditions This finding is consonant with the finding by aller gists of flare and wheal reactions in diag nostic testing that may be deemed of no clin ical significance Rather case histories are sought relative to allergens showing the strongest responses upon testing and treat ment may be confined to the use of several allergens or only those for which the case history indicates clinical disease In a few instances reagins have been detected 1 to 3 years before the onset of a corresponding clinical allergy

Several questions might warrant evalua tion (1) whether in addition to reagin some special concentration of it or alteration in a particular tissue site (shock tissue) is required to establish a clinical disorder (2) whether reagins can exist of low avidity (or affinity) that would give rise to less physio logic disturbance in mucous membranes than would be expected from their whealing re actions in the skin

HISTAMINE RELEASE FROM WHITE BLOOD CELLS In the last few years knowledge has grown concerning the multiple antigens of ragweed and grass pollens * these being sub jected to separation by modern biochemical technics and studied by immunoelectrophore sis versus rabbit antisera Aqueous ragweed extract for example contains more than 13 antigenic components not all of these being related to clinical sensitization As purer products become available it is found that very dilute solutions of certain fractions of *short ragweed as* 5×10^{10} *mg/ml induce* whealing in sensitive skin less than a 1 000th the amount of crude extractives (King and Norman 1962 King Norman and Connell 1964) Some ragweed-sensitive individuals appear to have coexisting sensitivities to more than a single constituent, since P K test sites after exhaustion of the capacity to react with purified material can still respond to whole extract (Arbesman *et al* 1962) The preparation of rather pure allergenic sub stances which are present only in small concentration in whole extract allows much more critical tests to be made than formerly were possible For example the coating of red cells with such products gives much higher titers than when many substances compete for the surface of the erythrocyte

Lichtenstein and Osler (1963) using the highly purified Antigen E of King *et al* (1962 1964) have been able to show his tamine release from the washed blood cells of ragweed sensitive patients at an allergen concentration of only 10^{-3} mcg/ml or less thereby confirming with 100- to 1 000-fold less material the pioneer findings of Van Arsdel and Middleton *et al* (1958) Middle ton *et al* (1960) VanArsdel and Middleton (1961) The antibody that is attached to the circulating white cells of allergic patients ap pears to be reagin both because it has been seen to decrease upon hyposensitization (VanArsdel and Middleton 1961) and be cause reaginic sera can sensitive passively normal human erythrocytes providing that serum is held at —70° C or is fresh (Van Arsdel and Sells 1963) Augustin (1962) concluded that reagins absorb both to nor mal leukocytes and to sheep erythrocytes The ratio of allergen to white blood cells is critical less histamine appearing when aller gen is in excess Divalent cations are re quired All human leukocytes were found to contain a soluble product which enhances *histamine release in this system*

BASOPHILE DEGRANULATION TEST In 1957 Rorsman noted that the number of

See Augustin and Hayward 1961 (orchard grass timothy pollens) cf Richter and Sehon (1960) Goldfarb and Callaghan (1961) King and Norman (1962) and Robbins *et al* (1963) on short ragweed pollen

basophilic leukocytes was decreased in the blood of patients with urticaria, he suggested that antigen antibody reactions or histamine liberating substances might degranulate these cells Subsequently Rorsman studied basophiles during allergic reactions of rabbits (1961) and guinea pigs (1962) In particular, he found that basophiles decrease if the anaphylactic shock of the guinea pig is mild or only moderately severe Shelley approached the problem by seeking to demonstrate basophile degranulation in vitro Shelley and Caro (1962) indeed found that addition of antigen (1% ovalbumin) to blood of sensitized rabbits degranulated a significant proportion of the basophiles in vitro and that these cells disappeared from the blood upon systemic shock

Turning to human allergic sera Shelley devised several technics to allow diagnostic use of such a test (1962 1963) The *indirect method* consists of using rabbit basophiles from selected New Zealand rabbits having 8 to 10 per cent of these cells passively coating the cells with sera of penicillin sensitive patients and observing the basophiles delineated by the vital dye neutral red for degranulation during exposure to allergen Positive results were reported in a narrow time range (1963a b) Several other types of hypersensitivity were tested with reports of positive results Although the method holds promise and many laboratories are engaged in study it is not presently perfected technically and indeed passive sensitization of rabbit cells with human reagins offers difficulty Some claims such as that prompt degranulation follows simple admixture of aspirin with basophiles and sera of aspirin sensitive patients deserve critical study

NONREAGINIC ANTIBODIES DESENSITIZATION Under natural conditions of exposure to pollens the allergic individual—the so called pretreatment patient —long had been thought to produce reaginic antibodies solely, these antibodies being multiple and corresponding to one or several of the allergenic substances within a given pollen

Yet with introduction of the passive hemagglutination technic in which the allergens are attached to the erythrocyte surface by diazotization through a benzidine bridge (via bis diazobenzidine or BDB) or are coated onto tanned red blood cells it was found that pretreatment patients possessed antibodies that agglutinated the erythrocytes to varying degrees but failed to precipitate ragweed proteins in vitro (Gordon Rose and Sehon 1958) If the serum globulins were concentrated 10 to 20 fold however direct precipitation was demonstrable (Perelmutter *et al*, 1962) Subsequently it became possible largely to separate the hemagglutinins apparently having properties of divalent precipitating antibodies from the reagins (Sehon 1962)

When allergic individuals have been subjected to desensitizing injections with their allergens in gradually ascending tolerated concentrations their posttreatment sera have been found to acquire a heat stable antibody designated as blocking antibody that combines readily and specifically with the allergenic material (Cooke *et al* 1935 Loveless 1940) The thermostable antibody neutralizes the allergen becomes a mixture of the two will fail to produce a positive skin test on a sensitive individual (Loveless 1940)—hence the name blocking or neutralizing antibody (Normal nonatopic individuals under the same treatment give rise somewhat less readily than allergic individuals to the same type of antibody reagin does not appear in the circulation but under intense antigenic stimulation Fisher and Connell (1963) observed a wheal and flare reactivity of transient nature)

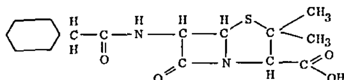
The higher titered specimens of blocking antibody were found to bind with allergen in complement fixation tests (Chap 9) then by diffusion in gel media these antibodies were seen to precipitate the allergen(s) Today the blocking antibodies are equated with the hemagglutinins mentioned above the apparent differences between nonprecipitating blocking antibody precipitins and hemagglutinating antibody being attributed to the concentrations in which they occur in different sera

In light of the recognition of blocking antibody as dilute precipitating antibody and the large number of antigens in ragweed that incite separate antibodies in rabbits it seems obvious that man under desensitization treatment will produce a variety of precipitins toward different constituents

Study of various aspects of the problems of desensitization doubtless will require that separated allergens be available

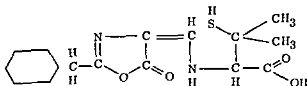
The presence of blocking antibodies in the serum of allergen treated patients can be determined after heat inactivation of the reagins by in vivo testing Conversely since blocking antibodies readily leave the skin after injection whereas reagin does not it is possible to measure reagin separately In order to test blocking antibody in vivo mixtures made with allergen are injected directly into sensitive or passively sensitized skin (The concentration of blocking antibody does not rise sufficiently high in patients possessing it to influence the occurrence of wheal and flare reactions upon cutaneous testing with allergens)

The idea that the process of desensitization is the development of a type of antibody other than the reagin the former protecting the patient by isolating newly absorbed allergen from sensitized tissues is still to be decided The complexity of pollens make the issue hard to resolve A more favorable situation for deciding the issue is offered by cases of insulin sensitivity coexisting reagin and thermostable antibody have been encountered the thermostable antibody appearing indeed to be responsible for periods of insulin fastness (Lowell 1944 1947 Loveless 1946 Berson *et al* 1956)



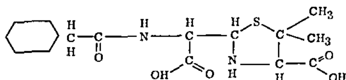
In attempting to desensitize the allergist is limited to the administration of very small amounts of pollen extract lest systemic accidents result The administration may be preseasonal in the case of flowering plants or it may be maintained throughout the year (perennial treatment) The idea that depot treatment—injection of large amounts of allergen in water droplets emulsified within a continuous phase of paraffin oil—would allow slow release of a greater amount of allergenic solutes and be more efficacious has come to the fore (Loveless 1957 Brown 1959) Unfortunately the idea of one shot injection therapy has dominated rather than a careful appraisal of the possible merits of the new type of treatment utilizing several injections Owing to improper emulsification or to instability of stored emulsions free allergen has been found at times in dangerous concentrations Nevertheless the method has yielded results that compare favorably with standard desensitizing procedures and study continues Other problems can arise as by provoking delayed type hypersensitivity to allergens p 287

NATURE OF THE REAGINS The thermolabile reagins in serum as has been seen above are accompanied by other immunoglobulins and they are dilute one estimate of the maximum concentration is 100 mcg / ml in those few sera that can give P K tests in 1 1 000 dilution (Gyenes and Sehon 1960) All early methods of fractionation indicated that reagins become more widely distributed over crude fractions than precipitins Further they have proved to be labile during biochemical fractionation and recovery of activity is low Again the number of specimens of reaginic serum that have been examined by modern methods is not large there is strong suspicion that a certain number of ragweed sensitive patients are sensitized to more than a single allergen of the extract The available evidence associates at least the major reagin of ragweed serum with β_A globulin and appears to exclude participation of β_M macroglobulin (19S) Some allergic individuals however are said to lack β_A globulin



Heremans (1960) and Augustin (1961) suggested the relation of reagins to β_A globulin and indeed Fireman Vannier and Goodman (1963) found reaginic activity to follow β_A globulins as they fractionated serum from treated ragweed sensitive individuals obtaining 10 per cent recovery Selective removal of β_{2A} globulins from entire serum by means of specific sheep antiserum gave a marked decrease in reaginic activity whereas a similar selective removal of gamma globulin left the original titer unaltered Ishizaka *et al* (1964) have found β_A globulins as the sole protein of the parotid duct along with the presence of reagin It may be added that most workers have found reagin to elute in column chromatography just ahead of gamma globulin this finding would be consistent with the determination of Rockey and Kunkel (1962) that the skin sensitizing antibody reacting with a highly purified glucagon sedimented faster than 7S antibody perhaps between 8 and 11S In

this case the reaginic property was inactivated by 0 1 M mercapto ethanol



In a new technic (Yagi *et al*, 1963), the proteins of reaginic serum were separated by electrophoresis and then precipitated in situ by antibody to human serum I^{131} labeled allergen being present Labeled allergen became bound to the precipitate its position being detected by autoradiography Insulin became bound to gamma globulin and at times to β_A globulins and a rather purified sample of ragweed allergens became bound to β_{2A} globulins and to gamma globulin and sometimes to β_M macroglobulin (Yagi *et al* 1963b) Obviously, it is not possible to know the participation of hemagglutinating and other nonreaginic antibody in these precipitates The same technic was applied in an

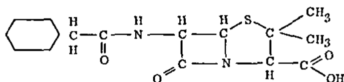
other form by Pruzansky *et al* (1962) a large amount of a highly purified I^{131} ragweed allergen binding in vitro to a precipitate formed by mixing reaginic serum directly with antihuman gamma globulin

REAGINS TO PENICILLIN Even though the more common form of hypersensitivity seen with penicillin is a delayed reaction resembling that of serum sickness explosive systemic reactions related to the presence of reagins can present grave danger and result in death Within 2 or 3 months after shock circulating reagins disappear the patient retaining cutaneous reactivity In testing actively sensitized persons or passively sensitized sites potassium penicillin G usually induces wheal and flare reactions (Schwartz and Vaughan 1963 VanArsdel *et al* 1963 Siegel 1962) but the reagins of 1 patient reacted only to stored procaine penicillin G solutions Of the proposed pathways through which (benzyl)penicillin reacts with host tissues successive conversions to penicillenic acid and then to penicilloic acid (Fig 5) have been postulated (Levine 1960 1961 Parker de Weck Kern and Eisen 1962) protein reactions occurring both via ε amino lysyl groups and SH groupings the latter products involving the SH of penicillenic acid and forming mixed disulfides

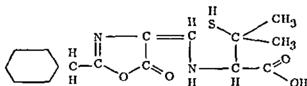
In order to detect immediate type reactivity to penicillin penicilloyl human gamma globulin conjugates have been employed in intradermal tests (Levine and Ovary 1961 Parker *et al* 1962) The most extensive investigations have been made with penicilloyl polylysine some preparations of which have contained not only penicilloyl groups but also a few penicillenate groups and penamaldate penilloaldehyde groupings newer preparations are virtually free of any but penicilloyl groupings (Parker Shapiro Kern and Eisen, 1962 Parker and Thiels 1963) Reactivity is expressed almost exclusively to the penicilloyl groupings and accordingly inhibition of cutaneous reactivity is usually demonstrable with ε penicilloyl aminocaproate (Recently Parker and Thiels 1963 have suggested that conjugates with polylysine made from the unnatural (D) amino acid may prove to be safer with respect to nonantigenicity of the complex) Yet about one half of reacting individuals respond to penicillenate conjugates as well reflecting the complexity of degradation reactions of penicillin in vivo When it is considered mandatory to make intradermal tests with penicillin G in order to reveal the most sensitive persons great caution must be exercised with use of scratch tests with 1 unit followed by intradermal tests with 1 5 and slightly higher unitage Only a few persons react in this way in contrast with the numbers reacting to tests with polylysine conjugate

In addition to reagins other types of antibodies to penicillin—both 7S and 19S—can be found in serum capable of agglutinating penicillin treated erythrocytes (Ley *et al* 1958 Schwartz and Vaughan 1963 Van Arsdel *et al* 1963) and fixing in guinea pig skin (PCA reactions) Indeed many individuals given penicillin form antibodies that can be detected by hemagglutination but without concomitant symptomatology or disease (Ley *et al* 1958) such antibodies arise also in rabbits injected with penicillin (Josephson 1960) In patients who give penicillin reactions the antibodies appear to be 7S and probably the antibodies are largely 19S in other persons



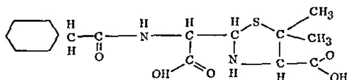
Asthma The problem of seasonal asthma differs from that of hay fever in the duration of attacks the basic reaginic mechanism being common to both Indeed progression from hay fever to asthma has been observed It has been alleged that in the asthmatic patient the tissue component can become altered pathologically through undergoing repeated allergic responses

In persons that have been termed horse asthmatics because of their responses to horse dander the hypertrophy of bronchial musculature frequently developing has been interpreted as rendering them particularly liable to respiratory symptoms and has been likened to the condition normally existing in guinea pig lung Kallos and Kallos Deffner (1937) found evidence of enlarged and emphysematous lungs in autopsy records of patients dying in asthmatic attacks and they pointed out that the special histologic character of the alterations in *Asthma bronchiale* rests on a peculiar allergic reaction of the bronchial wall and of the lung tissue (translation)



It could not be expected that prolonged

this case, the reaginic property was inactivated by 0 1 M mercapto-ethanol



In a new technic (Yagi *et al* 1963) the proteins of reaginic serum were separated by electrophoresis and then precipitated in situ by antibody to human serum, I^{131} labeled allergen being present Labeled allergen became bound to the precipitate its position being detected by autoradiography Insulin became bound to gamma globulin and at times to β_{1C} globulins and a rather purified sample of ragweed allergens became bound to β_{2A} globulins and to gamma globulin and sometimes to β_{2M} macroglobulin (Yagi *et al* 1963b) Obviously it is not possible to know the participation of hemagglutinating and other nonreaginic antibody in these precipitates The same technic was applied in an

Penicillamine

Fig 5 Some reaction products of penicillin G

serum albumin (Fig 4 B) can be shown to consist of human gamma globulin and complement

Proof that the gamma globulin is antibody in these lesions is mostly wanting as is true also in systemic lupus rheumatic fever rheumatoid arthritis and periarteritis nodosa Through recent studies however a definite relationship is coming to light between acute and subacute glomerulonephritis in man and preceding streptococcal infection Antigen that appears to represent streptococcal products especially of Type XII is found to be associated with glomerular membranes in acute disease In subacute glomerulonephritis antigen is less often detected but the globulin-complement deposits in the inter mesangial spaces seemingly have the capacity to bind fluorescein labeled Type XII streptococcal antigens (Seegal Andreas Hsu and Zabriskie 1964)

Dixon (1963) has further stressed that the sites in which complexes localize and cause injury do not reflect immunologic relationship between a complex and a tissue but are selected by local factors in the tissues and the character and the amount of complexes The existence of focal tissue injuries for example may cause localization of small complexes that otherwise would be clinically ineffective

Apart from the demonstration by fluorescence microscopy of host gamma globulin in lesions a search can be made for complexes present in the circulation Ultracentrifugation actually has disclosed the presence of gamma globulin containing complexes in the sera of patients primarily those with rheumatoid arthritis that are analogous to antigen antibody complexes (Kunkel *et al* 1961) Rheumatoid factors (19S 7S) which act like antiglobulin antibody complex with the patient s own 7S gamma globulin to give products in the ranges plus 22 S and 9–17S (Williams and Kunkel 1962 view the rheumatoid factor as antibody to buried determinants on normal gamma globulin) Likewise among patients with purpura subacute bacterial endocarditis idiopathic pulmonary fibrosis macroglobulinemia and so on gamma globulin-containing complexes have become to light

Auto antibodies in Allergy The thought that antibodies might arise to an individual s own tissues and react with cytotoxic effect is strengthened by supportive observations Much evidence has accumulated especially by use of fluorescing antihuman immune globulin antibodies (cf Coons 1956) that a patient s own gamma globulin affixes in sites of specific lesions—systemic lupus erythematosus and nephrotic glomerulonephritis (Mellors Ortega and Holman 1957) subcutane

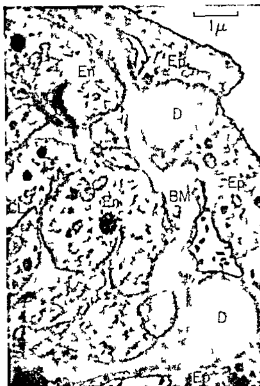

Fig 6 Portion of a glomerulus from an adult with subacute and chronic glomerulonephritis A part of one loop is visible (CL) Its lumen is filled with cytoplasm of swollen endothelial cells (En) The basement membrane (BM) is irregularly thickened and serpentine On its epithelial side are 2 dense deposits (D) resembling the deposits seen in rabbits with glomerulonephritis induced by injecting antigen over a prolonged period of time (see Fig 4) Epithelial foot processes have been replaced by sheets of cytoplasm (Ep) which cover both the deposits and the basement membrane (Drs Joseph D Feldman and F J Dixon)

asthmatic attacks would be explained by local release of preformed histamine for endogenous histamine should produce early and sharp reactions and mast cells would become exhausted A probable role of Slow Reacting Substance A' in human asthma has been predicted (cf Brocklehurst 1962 and Tables 2 and 3) since its release starts later than that of histamine and its concentration continues to mount 87 per cent of the contracting potency of lung perfusate at 30 minutes being referable to SRS-A Samples of freshly excised sensitive human lung either perfused with specific allergen or chopped and bathed in specific allergen released both histamine and SRS A exactly as did the lungs of sensitized guinea pigs or of sensitized monkeys The SRS A of both human and guinea pig origin caused contraction of human bronchioles in vitro in entire absence of tachyphylaxis hence a tissue subjected to repeated doses does not show any diminishing effectiveness A second possibility for persisting reactions in the asthmatic lung would be new formation of histamine by the inducible enzyme histidine decarboxylase (p 255) and a third possibility would be bradykinin (Tables 2 and 3), not yet demonstrated to arise in humans

Pointing once again to tissue changes in the lung tissue of asthmatics is the finding that aerosol inhalation of 0 5 per cent bradykinin reduces the vital capacity but even high doses are ineffective in nonallergic patients (Herxheimer and Stresemann 1961a)

As noted above the important finding that asthma can be produced in the *Macaca irus* monkey with human reagin offers a new tool in these studies

Physical allergies toward light (urticaria solaris) and toward cold are known Sera of such patients are found at times to permit transfer by the Prausnitz Kuestner procedure the prepared sites on the recipient being subjected respectively to irradiation with the proper wavelength of light or to chilling Such transfers show that an autologous substance must arise in the skin of all persons upon exposure only a very few persons developing hypersensitivity to it. Urticaria solaris probably may represent the oldest form of auto immune disease (Baer) The reagin is heat labile and often unstable and appears to be found in several serum fractions Thus after a reaginic serum in a case of physical allergy to cold had been separated into several protein fractions successful transfer was possible only by use of a mixture of component fractions (Sherman and Seebohm 1950) In reaginic type cold allergy Lennart and Shelley (1961) showed by punch biopsy that tissue mast cells underwent degranulation in chilled areas of skin releasing histamine

Among persons showing urticaria to light the reaginic factor is found chiefly in persons sensitive to the 2 800–3,200 A range of ultra violet and having an atopic background and reagins have been found also in certain but not all persons sensitive to the 4 000–5 000 A range of blue and violet light

Not all instances of urticaria due to light are allergic in nature one type seems to correlate with a heightened concentration of protoporphyrin IX in the skin, and some examples are referable to *phototoxicity* of ingested drugs such as sulfonamides and demethylchlortetracycline (Declomycin) (Epstein 1939, Harber *et al* 1961) But certain drugs and chemical compounds have proved to be *photo-allergic* in some individuals—the antihistamine promethazine (Phenergan) chlorothiazide (Diuril) sulfanilamide

Tissue Injury Studies on experimental animals already described (p 259) provide the current model for exploring tissue injury as a consequence of antigen antibody complexes Most often involved probably is the poorer antibody producer in whom antigen is not subjected to prompt immune elimination permitting soluble antigen antibody complexes to form and to persist It will be recalled that complexes can persist for long periods of time sequestered in the thickened basement membranes of the kidney glomerulus without causing acute inflammatory reactions Dixon points to concomitant persistence of associated renal malfunction lasting as long as a year i e , proteinuria (Dixon 1963)

An example of human subacute and chronic glomerulonephritis is shown in Figure 6 The segregated dense deposits resembling in location and size those arising in rabbits injected for months with bovine

antibodies can be involved—being either complete incomplete or hemolytic (with complement) and others are active between 4 to 16° or more being macro globulins (19S) of the cold variety utiliz ing complement In patients that recover owing to treatment the antibodies disappear

The origin and the significance (in terms of allergic episodes) of certain other impor tant factors found in the serum of patients have not yet been determined Patients with lupus erythematosus (L E) possess a gamma globulin which is responsible for the forma tion of the bizarre L E cell that appears in the blood the factor fixing to the nuclei (Miescher *et al* 1954 Holman and Kunkel 1957) of polymorphonuclear leukocytes which then form a swollen body become free and undergo ingestion by normal polymor phonuclear leukocytes The factor fixes to the separated nuclei of several species and is viewed as an auto antibody to nucleoprotein or deoxyribosenucleic acid (cf Robbins *et al* 1957)

The idea has been voiced that some allergic diseases may occur without participation of any antigen Thus if molecular changes should arise in gamma globulin that would allow these molecules to aggregate comple ment fixation could take place resulting in nonspecific agglutination of red cells and platelets in the absence of antigen and anti body (Ishizaka *et al* 1961 1962)

To study auto immune diseases various laboratory models have been used many using antigens that differ from those of the subject animal itself Often denatured autol ogous proteins are used as antigen or nor mal tissue is injected with mycobacterial paraffin oil adjuvant or guinea pigs whose tissues contain Forssman antigen are injected with anti Forssman immune globulin Hal pern *et al* (1963) have injected papain re peatedly into monkeys and rabbits leading to destructive alterations in the tissues and a finding of antibodies toward tissue structures containing glucoproteins In one model a graft versus host reaction (p 289) is estab lished by appropriate cellular transfer and the pathologic events occurring in runt dis ease are noted The value of such study in volving erythema purpura acanthosis and various extreme lesions as well as the histo logic resemblances to lupus erythematosus and scleroderma has been stressed by Stastny *et al* (1963)

ALLERGIC INFLAMMATION DELAYED RESPONSES

Allergic reactions that require some hours to become manifest after the test material is applied are placed in a separate category not because of the delay in development but rather because they exhibit no readily de monstrable relation to circulating antibodies and the procedure of passive transfer by means of serum is typically unsuccessful Transfer with white cells in contrast has been demonstrated in several key instances without direct evidence of circulating im munoglobulin (Table 1) The coexistence of a delayed type of response and a circu lating antibody has been noted in some cases which is not surprising since the stimuli giv ing rise to delayed type hypersensitivity ex cites the antibody forming apparatus as well even if not in an equal degree

Dermal sensitivity is induced chiefly by percutaneous absorption following contact of the skin with substances of low molecular weight (simple chemical substances nickel salts urushiol from the poison ivy plant and the like) or with products of fungi growing superficially in the skin Upon a subsequent exposure to the same agent there appear reactions of eczematous type such as hy peremia macules papules or even vesicles as the epidermis separates and fluid accumu lates beneath itching can occur as well His tologically there is infiltration with lympho cytes and monocytes giving rise to indura tion as contrasted with the edema seen in immediate type reactions

Invasion of the body by a variety of infec tive agents (bacteria fungi parasites viruses etc) establishes hypersensitivity around foci of infection The presence of hypersensitivity is detected by injecting various extractives or metabolites of the infectious agent (or entire viral suspensions) into the skin (cf Jadassohn 1932) with resulting cellular in filtration hyperemia and gradually increas ing induration

ous nodules of rhematoid arthritis and heart valves in fatal rheumatic fever (Vazquez and Dixon 1956)—and often there is no known alteration in the tissues *to suggest the reason* for auto antibody formation

It is first necessary to set apart instances in which the antigenic stimulus is provided *from without the body* as in the production of thrombocytopenic purpura by the administration of allergenic drugs

In studying thrombocytopenic purpura that followed the ingestion of the drug Sedormid Ackroyd (1949 1955) found an antibody that agglutinated and evidently lysed the patient's platelets whenever the drug was ingested In vitro studies on the resulting antibody drug platelet complex have been possible in both Sedormid and quinidine hypersensitivities (Ackroyd 1955 Dausset 1957 Bolton 1956 Shulman 1958) The antibody fixes complement It attaches so loosely to the platelet that is freed by dialyzing away Sedormid

The idea has been advanced that group A streptococci contain an antigen immunologically related to human heart tissue and may give rise to antibodies that function as organ specific auto antibodies (Kaplan, 1962 cf Cavelti 1947) this could perhaps explain the finding of antibodies fixed in the heart tissues of persons dying of acute rheumatic fever

In other areas the alteration of tissues by disease or mechanical trauma could lead to the formation of nonself' products of potential antigenicity

Thus *Schwentker and Rivers (1934)* showed that monkey brain—usually altered by autolysis or viral infection—was antigenic in monkeys their work led directly to experiments that resulted in production of iso allergic encephalomyelitis for which a highly artificial adjuvant system is now employed (this disease will be discussed later) The same device—the use of dead mycobacteria *in paraffin* oil and tissue maintained in water droplets for slow release—leads to autosensitization vs thyroid (Witebsky and Rose 1956) testis (Voisin *et al* 1951 Freund *et al* 1953) and so on In all of these states antibody is demonstrable but does not appear to play a chief role

Often however there is no clue as to the 'antigen' that gives rise to auto antibody For example in idiopathic thrombocytopenic *purpura (ITP)* a plasma factor has been demonstrated leading to a marked and prompt reduction in the numbers of platelets in transfused normal volunteers and producing frankly hemorrhagic manifestations in some of them (cf Harrington Minnich Hollingsworth and Moore 1951 Harrington Minnich and Arimura, 1956) the activity is found to reside in the globulin fraction (Evans *et al* 1951) Yet there is no good in vitro technic for studying the ITP plasma factor such as that which exists for the anti platelet antibodies induced by drugs

Indeed the view that antigen should be some altered body constituent capable of inciting antibody production has been doubted The alternate theoretical view—by no means proved—is that special cell lines having potential antibody forming capacity remain within exceptional individuals under some sort of control (tolerance is alleged) but eventually come to react to say the individual s erythrocytes and form antibody against entirely normal cells This explanation is advanced to explain the fate of a particular strain of mouse the New Zealand Black in which all animals eventually develop auto immune hemolytic anemia some showing lupus nephritis also (Bielschowsky Helyer and Howie 1959 Helyer and Howie 1963) In this disease in which antibodies attaching to the red cells come to be formed by splenic cells between 4 and 12 months of age (cf Holmes Gorrie and Burnet 1961) outbreeding was seen to alter the age of onset and made the predominant feature sometimes lupus nephritis with renal failure sometimes hemolytic anemia In man too attention is being paid increasingly to susceptibilities within family groups—for example toward auto immune thyroiditis

Auto immune hemolytic anemia of man is a disease seemingly having no intimate relevance to hypersensitivity globulins become adsorbed to erythrocytes, resulting in early removal and anemia and often ending in death The antibodies encountered among patients fall into various types Some are active at 37°—both γ globulin and non-γ Rh

antibodies can be involved—being either complete incomplete or hemolytic (with complement) and others are active between 4 to 16 or more being macro globulins (19S) of the cold variety utiliz ing complement In patients that recover owing to treatment the antibodies disappear

The origin and the significance (in terms of allergic episodes) of certain other impor tant factors found in the serum of patients have not yet been determined Patients with lupus erythematosus (L E) possess a gamma globulin which is responsible for the forma tion of the bizarre L E cell that appears in the blood the factor fixing to the nuclei (Miescher *et al* 1954 Holman and Kunkel 1957) of polymorphonuclear leukocytes which then form a swollen body become free and undergo ingestion by normal polymor phonuclear leukocytes The factor fixes to the separated nuclei of several species and is viewed as an auto antibody to nucleoprotein or deoxyribosenucleic acid (cf Robbins *et al* 1957)

The idea has been voiced that some allergic diseases may occur without participation of any antigen Thus if molecular changes should arise in gamma globulin that would allow these molecules to aggregate comple ment fixation could take place resulting in nonspecific agglutination of red cells and platelets in the absence of antigen and anti body (Ishizaka *et al* 1961 1962)

ALLERGIC INFLAMMATION DELAYED RESPONSES

Allergic reactions that require some hours to become manifest after the test material is applied are placed in a separate category not because of the delay in development but rather because they exhibit no readily de monstrable relation to circulating antibodies and the procedure of passive transfer by means of serum is typically unsuccessful Transfer with white cells in contrast has been demonstrated in several key instances without direct evidence of circulating im munoglobulin (Table 1) The coexistence of a delayed type of response and a circu lating antibody has been noted in some cases which is not surprising since the stimuli giv ing rise to delayed type hypersensitivity ex cites the antibody forming apparatus as well even if not in an equal degree

Dermal sensitivity is induced chiefly by percutaneous absorption following contact of the skin with substances of low molecular weight (simple chemical substances nickel salts urushiol from the poison ivy plant and the like) or with products of fungi growing superficially in the skin Upon a subsequent exposure to the same agent there appear reactions of eczematous type such as hy peremia macules papules or even vesicles as the epidermis separates and fluid accumu lates beneath itching can occur as well his tologically there is infiltration with lympho cytes and monocytes giving rise to indura tion as contrasted with the edema seen in immediate type reactions

Invasion of the body by a variety of infec tive agents (bacteria fungi parasites viruses etc) establishes hypersensitivity around foci of infection The presence of hypersensitivity is detected by injecting various extractives or metabolites of the infectious agent (or entire viral suspensions) into the skin (cf Jadassohn 1932) with resulting cellular in filtration hyperemia and gradually increas ing induration

The 'delay' in onset of reactions both in testing for contact dermatitis and for tuberculin type allergies appears to represent the time required for white cells to leave the vessels accumulate at the test site and react there with the test material There seems to be no inherent sensitiveness of the skin (Frei 1928 Landsteiner *et al*, 1948 Livingood 1952 Curtis 1952) Indeed in transplanting skin between twins one of whom had been sensitized to dinitrochlorobenzene Haxthausen (1943) observed that skin of the normal brother exhibited hypersensitivity after being grafted to the sensitive twin and, conversely that a skin graft from the sensitized brother to the normal twin showed no capacity to react

Further discussion of mechanisms will be given below Here it is useful only to note that the term cell bound antibody has unfortunately arisen conjuring up the picture of lymphocyte or monocyte carrying preformed antibody firmly bound to it There is little evidence that this is the situation according to one recent report continued synthetic function of the competent cell may be required to effect reaction with allergen (Bloom *et al* 1964)

It would appear from the several aspects of delayed hypersensitivity (which too often are studied singly) that allergic conversion is associated with (1) an altered behavior of lymphoid cells (2) an altered behavior of macrophages and (3) often a stimulation to form immunoglobulins Without doubt future studies will put these into sharper focus

The hypersensitive state related to infectious processes will be considered first The outstanding example of reactions of delayed type was provided by Koch s discovery in 1891 of the tuberculin tuberculosis relationship although the underlying allergic basis was not recognized until 1903 (von Pirquet) Owing to several confusing factors a clear distinction between the tuberculin reaction and reactions of the anaphylactic type was drawn only much later (Coca 1920 Calmette 1920 Zinsser 1921)

Tuberculin Hypersensitivity

In Koch s experiments tuberculous guinea pigs were found to possess a special reactivity when superinfection was attempted At the subcutaneous injection site there occurred a massive inflammatory reaction of the tissues, walling it off within 3 days and usually leading to slough—the Koch phenomenon ' Since living cells were not necessary, Koch sought a bacterial extract possessing the same property and attained it by heating the mycobacteria for some hours in the medium in which they had grown (meanwhile concentrating the fluid), and finally removing the bacterial residue Injection of this preparation called O T or old tuberculin caused a severe to lethal shock of delayed type termed the systemic reaction A *local* reaction occurred not only as a papule in the skin where the injection had been made but also along the needle track and the draining lymph nodes were discolored and enlarged There were also *focal* reactions of inflammation around existing tuberculous lesions with dense leukocytic infiltrations and with hemorrhagic exudate in serous cavities The focal reactions seem to give rise to the general toxemia and death

In 1903 von Pirquet advanced the hypothesis that tuberculin shock was another of the phenomena of sensitization and this belief led him to the discovery in 1907 of the *cutaneous tuberculin reaction,* so important diagnostically A delayed type of *ocular reactivity* was noted almost simultaneously Thus the relatively avascular cornea of tuberculous guinea pigs reacts to direct injection of tuberculin (Holley 1935 Rich and Follis 1940) with edema swelling of the fibers infiltration with granulocytes and necrotization of corneal cells

Indeed the 4 types of response—local focal ocular and systemic—remain as our most stringent criteria of delayed type hypersensitivity to water soluble allergens but such critical tests are possible only in sensitized laboratory animals *local* reactions at the site of skin tests showing induration at 48 hours *systemic* reaction to injections made by the peritoneal or intravenous routes, and *corneal* reactions resulting from intracorneal injection Even in diagnostic testing by intracutaneous injection (Mantoux) it is necessary to select the dosage of tuberculin with caution for an excess of tuberculin may cause not only unduly severe reactions in the skin but also some degree of lighting up

around tuberculous lesions and febrile systemic reactions (Tytler 1930)

Obviously bacteria offer numerous antigens to the invaded host In the case of *Myco tuberculosis* circulating antibodies to perhaps 7 of these have been discovered by the application of special technics (Boyden and Sorkin 1956) although the concentration of the antibodies is seldom high Indeed one of the early difficulties in interpreting the tuberculin reaction had to do with the occasional demonstration of an anaphylactic state in tuberculous guinea pigs It is now rather well agreed that these antibodies are not causally related to the delayed type hypersensitivity Several of the tuberculoproteins tested in their native state elicit cutaneous delayed type reactions one being heat-coagulable and of large molecular size (ca 44 000) For the purpose of human skin testing it would seem to be desirable to elect low molecular and even heat altered material as long as it is serologically reactive in order to avoid the acquisition of sensitiveness to proteins through repeated skin testing Present practice however is to prepare the testing materials such as PPD (purified protein derivative) from culture filtrates that approach the native state

When suitably diluted tuberculin is injected into the skin of the tuberculous individual redness appears after some hours and the local inflammation with its associated infiltrate gradually increases in intensity and extent for from 15 to 48 hours and attains a typical firm induration when the dose and the degree of sensitivity cause a more severe reaction there are central blanching and a gradually developing innermost livid zone which often becomes necrotic The inflammation slowly fades but the lesion is palpable for some days and pigmentation may be seen for several weeks

Histologically the reaction to tuberculin is attended by characteristic focal accumulations of mononuclear cells (Dienes and Mallory 1932 Laporte 1934 Fisher to be published) In tuberculous guinea pigs Fisher found that lymphoid cells left the vessels in the corium and migrated upwards toward the epidermis and the hair bulbs Within 12 hours the epidermis became acanthotic and the lymphoid cells formed focal accumulations (spongiosis) with vesiculation and perivascular granulomas appeared in the corium Hyperplasia occurred in the papillary cells of the hair roots along with destruction of the hair bulbs causing loss of hair (When sensitization is effected by using dead mycobacteria in paraffin oil other features are noted in addition probably owing to participation of immunoglobulins) Studies of tuberculin reactions in rabbits by Gell and Hinde (1951 1954) showed proliferation and differentiation of the infiltrating monocytes and also of local histiocytes and mesenchymal cells From their studies with rabbits sensitized with dead mycobacteria and hydrocarbon—this species producing antibody in high concentration—these workers were less inclined than others to distinguish between Arthus and purely tuberculin reactions Indeed when necrosis results from tuberculin reactions there are no differentiating histologic features between severe tuberculin and Arthus reactions

By injection of killed mycobacterial cells it is possible to induce only low grade sensitivity to tuberculin but there is remarkable enhancement of sensitization when the dead bacilli are suspended in hydrocarbons such as paraffin oil Many attempts had been made to obtain a bacillary extract capable of substituting for the whole killed cells in inducing the delayed type of hypersensitivity Finally Raffel found a wax fraction of the cells in conjunction with tuberculoprotein present as an impurity or intentionally admixed to possess the property sought (cf Myrvik and Weiser 1952) The directive effect of the wax in inducing sensitization to tuberculin appears to be dependent on its lipopolysaccharide Choucroun (1939 1947) had separated a lipopolysaccharide that gives rise to delayed type hypersensitivity while Asselineau and Lederer (1949) extracted wax D from human tubercle bacilli its counterpart in bovine strains remaining bound to the cell walls Wax D both sensitizes to tuberculin and possesses the adjuvant property of mycobacteria It is a peptidoglycolipid containing mycolic acid joined in ester linkage to a polysaccharide composed of arabinose mannose galactose glucosamine and galactosamine and through the hexosamine to a heptapeptide containing

alanine glutamic acid glycine and α, ϵ diaminopimelic acid (Asselineau, Buc Jolles and Lederer 1958)

After a single large injection of tuberculin has produced severe constitutional reactions desensitization—usually incomplete—is found in tuberculous animals and human beings Desensitization is peculiarly hazardous because of the danger of focal reactions but desensitization by repeated gradually increasing doses of tuberculoprotein has often been carried to a point at which the patients were able to tolerate without a focal or constitutional reaction, doses of the protein which in the undesensitized body would undoubtedly have produced extreme focal reactions and death (Rich 1951) The desensitization of tuberculous guinea pigs is a difficult task requiring large repeated doses of the tuberculin preparation PPD, but during the treatments the skin is maintained truly nonreactive and it even will react to intradermal spread of dyes in the same way as does normal skin (Birkhaug and Berle 1945) However, sensitivity returns when administration is discontinued

Cellular sensitivity to tuberculin was observed by Rich and Lewis (1928 1932) it was evidenced by a decided inhibition of migration of the allergic cells from the explant into the surrounding tuberculin containing plasma and by the fact that the relatively few cells which do wander out die in a few hours Confirmation has been forthcoming when proper concentrations of tuberculin are used but cells of well sensitized individuals are required (cf Aronson, 1931 Moen and Swift 1936, Heilman 1944 Waksman 1953 Florio *et al* 1958 Hall and Scherago 1957) Apparently sensitivity of macrophages is evident even in their descendant or daughter cells at least of the immediately succeeding generations (Moen 1936) and sensitivity of fibroblasts is variable but often trivial It is not surprising in view of failure to find inherent sensitiveness of the skin that sensitivity is not seen in cultures of corneal epithelial cells or cutaneous or hepatic epithelium (cf May and Weiser 1956)

Yet not until 1945 was it recognized that living white cells of tuberculin sensitive animals serve to transfer the delayed type of reaction to another animal of the same species (Chase, 1945, Cummings *et al*, 1947, Stavitsky 1948) Competent cells contained in peritoneal exudates lymph nodes spleens or blood would induce hypersensitivity to tuberculin for 5 to 9 days termination appeared to depend on homograft type rejection of the transferred cells for transfers between isologous guinea pigs were durable (Chase, 1960 1963 Bauer and Stone, 1961) Further, Kirchheimer and Weiser (1947) showed that systemic reactivity to tuberculin is transferable likewise by means of cells (cf Kirchheimer *et al* 1949, Wesslen 1952) It is highly probable that analogous transfers were encountered in older attempts since tissue and white cells were often included inadvertently in the material transferred (cf Bail 1910 Fellner, 1919), but the experiments were discounted because they lacked reproducibility

When transfer is made by injecting large numbers of competent cells intradermally into normal recipients special observations have been possible If rather large amounts of tuberculin were given parenterally tuberculin reactions (probably with participation of a Shwartzman effect) occurred in the sites of cellular deposition in both guinea pigs and rabbits (Metaxas and Metaxas Buhler 1948, 1949 Wesslen 1952) It was shown that mixtures of cells and tuberculin were fully effective when injected intradermally (Metaxas and Metaxas Buhler 1955) By means of the latter technic mixtures of tuberculin and competent rat cells reportedly have given effective reactions in guinea pig recipients a first instance of crossing the species barrier (Bacon Dabney and Wallace 1961 cf Wallace, 1958)

Under normal conditions of cellular transfer, in which cells must survive and escape from blood vessels to the test site no large number of donor cells (labeled proportionately by tritiated thymidine) is found to participate The processes leading to cellular damage in the test site are largely unknown but will be discussed below

More recently, intensive study has begun on the direct reaction in vitro between competent cells and tuberculin Cellular migration from explants of macrophages taken up to 10 months following sensitization was

inhibited consistently in tests with 10 mcg /ml tuberculin PPD and sensitivity was seen to spread gradually from cells of the nearest lymph nodes to splenic cells and hepatic macrophages (Carpenter 1963) Using macrophages and lymphocytes packed in capillary tubes David *et al* (1964) studied cellular outgrowth into culture medium containing PPD Not only were sensitive cells specifically inhibited but all migration was blocked provided that as little as 2 5 per cent of tuberculin sensitive cells were mixed with normal cells

A phenomenon of lympholysis was de scribed by Favour (1947) When tuberculin was mixed with lymphocytes from tubercu lous mice a loss of 20 to 40 per cent of these cells occurred in less than 1 hour The effect appears to depend on an antibody present in tuberculous plasma and serum comple ment is required for lysis In guinea pig and man granulocytes and large mononuclear cells are lysed also but more slowly The serum factor has been stated to be released by the tuberculin sensitive lymphocytes upon incubation in normal plasma (Miller and Favour 1951) In studies by Waksman (1953) and Waksman and Bocking (1954) inhibition of macrophages in tissue culture and not lympholysis paralleled dermal re activity to tuberculin (cf Waksman s exten sive review 1958)

A wholly different phase of sensitization—a slow synthesis of gamma globulin—has been emphasized by studies of lymphocytes in culture following the addition of allergen As Pearmain Lycette and Fitzgerald (1963) showed with tuberculin and is now well con firmed (cf Hirschhorn *et al* 1963a b) lymphocytes of persons with delayed type hypersensitivities when exposed to the allergen in maintenance culture are found to respond with significant changes in 5 days they aggregate increase in size and synthesize gamma globulin show mitotic figures (0 6 to 3%) and blast cell formation (3 to 20%) and some cells come to resemble plasmocytes For undiscovered reasons normal lymphocyte cultures are stimulated to undergo this same sequence of changes starting within 4 hours and completed in 3 days upon addition of a leuko agglutinin present in crude phytohemagglutinin or lectin Nearly every cell responds to leuko agglutinin but in the case of hypersensitive donors only a proportion of the total cells reacts to specific allergen (5 to 35%) prob ably those that are immunologically com petent cells The observation may well bear on the acquired capacity for antibody pro duction that follows the onset of delayed hypersensitivity Boyden and Suter (1952) showed for example that in tuberculous guinea pigs cutaneous testing with tuberculin stimulates production of circulating antibody within 5 days Whatever the relation to de layed type hypersensitivity may prove to be the ability to discover the causal allergen should make this technic a powerful tool

Quite novel aspects of tuberculin hyper sensitivity diverging in several respects from the above account have been forthcoming from studies in man chiefly by Lawrence By cellular transfer of small volumes of white cells from the peripheral blood Lawrence reported transfer in man of tuberculin (1949) and of streptococcal (1952) hyper sensitivities Lawrence then found (1954 1959 1960) that lysates of the cells induced sensitization which was unaffected by ex posure to deoxyribonuclease ribonuclease or trypsin Because the induced sensitivity was found to persist for many months and successive serial transfers were possible using recipients cells lyzed in turn the concept of a replicating transfer factor was de veloped to explain the retained sensitivity in later cell generations Transfer factor is liberated when cells are incubated with tuber culin no evident damage occurring to the cells and it is readily separable from DNAse treated cells by passage through dialysis membranes The active material has a molec ular weight of 10 000 or less and is un affected by ribonuclease it is not a protein (Lawrence *et al* 1963) The subject now is opened to identification of the active ma terial and an understanding of the mechanism by which it operates

If as has been stated transfer factor is unique for the human being human mono cytes still react to tuberculin as explants the points at issue concern (1) replication in vivo (2) the existence of a preformed dis sociable factor bound to lymphocytes (3) the apparent loss by living lymphocytes of

alanine glutamic acid, glycine and α ε-diaminopimelic acid (Asselineau Buc Jollès and Lederer 1958)

After a single large injection of tuberculin has produced severe constitutional reactions desensitization—usually incomplete—is found in tuberculous animals and human beings Desensitization is peculiarly hazardous because of the danger of focal reactions but desensitization by repeated gradually increasing doses of tuberculoprotein has often been carried to a point at which the patients were able to tolerate without a focal or constitutional reaction doses of the protein which in the undesensitized body, would undoubtedly have produced extreme focal reactions and death (Rich 1951) The desensitization of tuberculous guinea pigs is a difficult task requiring large, repeated doses of the tuberculin preparation PPD but during the treatments the skin is maintained truly nonreactive and it even will react to intradermal spread of dyes in the same way as does normal skin (Birkhaug and Berle 1945) However sensitivity returns when administration is discontinued

Cellular sensitivity to tuberculin was observed by Rich and Lewis (1928 1932) it was evidenced by a decided inhibition of migration of the allergic cells from the explant into the surrounding tuberculin-containing plasma and by the fact that the relatively few cells which do wander out die in a few hours Confirmation has been forthcoming when proper concentrations of tuberculin are used but cells of well sensitized individuals are required (cf Aronson 1931 Moen and Swift, 1936, Heilman, 1944 Waksman 1953 Florio *et al* 1958 Hall and Scherago, 1957) Apparently sensitivity of macrophages is evident even in their descendant or daughter cells, at least of the immediately succeeding generations (Moen 1936) and sensitivity of fibroblasts is variable but often trivial It is not surprising in view of failure to find inherent sensitiveness of the skin that sensitivity is not seen in cultures of corneal epithelial cells or cutaneous or hepatic epithelium (cf May and Weiser, 1956)

Yet not until 1945 was it recognized that living white cells of tuberculin sensitive animals serve to transfer the delayed type of reaction to another animal of the same species (Chase 1945, Cummings *et al* 1947 Stavitsky, 1948) Competent cells contained in peritoneal exudates lymph nodes spleens or blood would induce hypersensitivity to tuberculin for 5 to 9 days termination appeared to depend on homograft type rejection of the transferred cells for transfers between isologous guinea pigs were durable (Chase 1960, 1963 Bauer and Stone 1961) Further Kirchheimer and Weiser (1947) showed that systemic reactivity to tuberculin is transferable likewise by means of cells (cf Kirchheimer *et al*, 1949 Wesslen 1952) It is highly probable that analogous transfers were encountered in older attempts since tissue and white cells were often included inadvertently in the material transferred (cf Bail 1910 Fellner 1919) but the experiments were discounted because they lacked reproducibility

When transfer is made by injecting large numbers of competent cells intradermally into normal recipients special observations have been possible If rather large amounts of tuberculin were given parenterally tuberculin reactions (probably with participation of a Shwartzman effect) occurred in the sites of cellular deposition in both guinea pigs and rabbits (Metaxas and Metaxas Buhler 1948 1949 Wesslén 1952) It was shown that mixtures of cells and tuberculin were fully effective when injected intradermally (Metaxas and Metaxas Buhler 1955) By means of the latter technic mixtures of tuberculin and competent rat cells reportedly have given effective reactions in guinea pig recipients a first instance of crossing the species barrier (Bacon Dabney and Wallace 1961 cf Wallace 1958)

Under normal conditions of cellular transfer in which cells must survive and escape from blood vessels to the test site no large number of donor cells (labeled proportionately by tritiated thymidine) is found to participate The processes leading to cellular damage in the test site are largely unknown but will be discussed below

More recently intensive study has begun on the direct reaction in vitro between competent cells and tuberculin Cellular migration from explants of macrophages taken up to 10 months following sensitization was

tially purified culture filtrate rich in the enzymes streptokinase and streptodornase

Allergy to streptococci has been well studied in laboratory animals In natural in fections with group C streptococci there is pronounced skin reactivity to streptococcal extracts in guinea pigs that are ill with epizootic lymphadenitis or are healthy car riers of the responsible microorganism (Moen 1936b) and there is reactivity in rabbits to extracts of their natural pathogen *Past cuniculicida* the organism causing snuffles (Hanger 1927)

Delayed type hypersensitivity can be estab lished in rabbits with *viridans* streptococci by intracutaneous injection and by several other routes but not by intravenous injection Apparently in connection with the development of some focal tissue reaction the animals presented cutaneous ophthalmic and systemic hypersensitivity to the admin istration of living streptococci all being ex pressions of a delayed type of reaction un related to the amount or the type of circulating antibody and not transferable by serum

To relate further the mechanisms of strep tococcal and tuberculin hypersensitiveness Moen (1936a) examined both sorts of sensi tivity in parallel in tissue culture using ex plants of tuberculous tissues and explants of the spleen of guinea pigs infected with a natu ral streptococcal pathogen (group C hemo lytic streptococci from guinea pig lymph adenitis) The presence of streptococcal extract led to a slowly developing specific toxic effect on the cells of streptococcus infected animals quite similar to but quan titatively less than that of tuberculin on tuberculin sensitive cultures The strepto coccus sensitive cells exhibited more unequal gradations of sensitivity than were seen in tuberculin sensitive cultures some cells being killed rapidly others being only slightly in hibited Very much less evidence of persisting sensitivity was seen in subcultures of the streptococcus sensitive cells as compared with explants of tissues from tuberculous animals

As mentioned above Lawrence (1952) has reported transfer of streptococcal hyper sensitivity from man to man by means of peripheral blood leukocytes

Pneumococcal Allergy Pneumococcal allergy has been studied in much the same way as has streptococcal hypersensitivity Deposition of vaccine in the skin of rabbits leads to a delayed type of skin reactivity to ward pneumococcal vaccine or nucleoprotein and a delayed type of ocular reactivity (Julianelle 1930 Harley 1935 1937) the manifestation of reactivity to nucleoprotein is passively transferable by means of serum and apparently is of Arthus type whereas neither the allergy to vaccine nor the eye reaction is so transferable In contrast the injection of intact cocci by the intravenous route leads to the development of anticarbo hydrate antibodies and to immediate type reactivity expressed toward the correspond ing polysaccharide

During the course of pneumococcal pneu monia 2 types of specific skin reaction were observed (Tillett and Francis 1929) one being in response to the type specific capsular polysaccharide and appearing at the onset of convalescence consisting of an immediate reaction of urticarial type and the other elicited by species specific nucleoprotein and being of the tuberculin type A 3rd type of reaction can be produced by intradermal tests with somatic C polysaccharide of pneumococci during a limited period of the disease the reaction depends on a special protein (termed the C reactive protein) which appears as a consequence of many acute infections not only with the pneumo coccus and happens to react with C poly saccharide even in vitro An analogous factor not capable of reacting directly with C polysaccharide appears also in animals during acute inflammatory responses viz to typhoid vaccine (Kushner and Kaplan 1961)

SKIN TESTS

To make any test practicable for diagnosis it is necessary to use relatively purified preparations to know the proper doses with respect both to tissue irritation and concen trations that will not cause focal reactions in positive reactors and to understand the specificity of the reaction It must also be known whether the material employed for skin testing can lead to active sensitization and vitiate future tests Even in the most

their property of effecting transfer after transfer factor has been dissociated (4) the relation of the small nonprotein molecule to synthetic functions awakened by immunologic stimulation and (5) the functional specificity of transfer factor Transfer factor appears not to have been encountered in animals (Bloom 1963) previous reports seemingly being explained by technics of testing the animals

Allergy in Microbial Diseases Other Than Tuberculosis

In other microbial infections (with bacteria fungi viruses) and in certain parasitic infestations there is exhibited much the same sort of delayed type reactions when the corresponding agents or extracts thereof are put into the skin In variable degree one finds also the other chief attributes of delayed type sensitization—systemic reactions sensitivity of the cells in tissue culture toward the respective allergens and characteristic damaging reactions upon intracorneal injection However many reactions are less pronounced than in the tuberculin tuberculosis relationship for as Boyd has remarked tuberculin allergy is one of the more extreme examples of bacterial allergy Furthermore one finds the early type of sensitivity far more frequently the extracts employed for testing sometimes giving immediate type reactions particularly in relation to a content of specific polysaccharides Often both types of sensitization coexist probably related to different constituents of the test material

The degree to which microbial allergies may shape the disease pattern has been long debated Fundamental studies regarding the effect of delayed hypersensitivity on invading microorganisms were made in mice by Mackaness (1962) When *Listeria monocytogenes* selected for virulence and multiplication within macrophages was injected in sublethal numbers intracellular multiplication progressed to the 4th day and then ceased abruptly Delayed type hypersensitivity appeared at this time demonstrable by the reactivity of the footpad to culture filtrate and coincidentally macrophages showed accelerated mitotic activity destruction of bacteria and resistance to superinfection Similarly intense mitotic activity was caused in the peritoneal macrophages of hypersensitive mice when culture filtrate was injected Seemingly the altered macrophages accounted for the resistance of convalescent mice to challenge Resistance continued for a few weeks and then gradually diminished even though hypersensitivity persisted As long as hypersensitivity was present there was capacity to give an accelerated response to reinfection perhaps through formation of a new population from surviving hypersensitive macrophages In general however, it is not possible to isolate so clearly the processes ensuing after invasion by microorganisms and the role played by hypersensitivity usually has remained indeterminate In the same way a greater destruction of tubercle bacilli occurs in vitro within macrophages of hypersensitive animals than within normal macrophages (cf review by Elberg 1960 Suter 1953 1954 Fong *et al* 1957 1963) but the role played by white cells in delayed type hypersensitivity probably exceeds that of intracellular digestion by monocytes It may be noted that immunity to tularemia appears to have been passively transferred briefly by spleen cells and peritoneal leukocytes (Allen 1962)

Streptococcal Allergy Evidence of infection with streptococci usually is sought in the form of circulating antibodies directed against streptococcal enzymes and type specific antigens However preceding infection can be witnessed by delayed type allergy toward streptococci Relatively large samples of the population have been tested by means of killed streptococcal cells (vaccines) cellular substances (nucleoprotein M substance) and culture filtrates Mackenzie and Hangar (1927) found the incidence of sensitivity to increase gradually with age and superimposed upon this finding a sharp rise in the number of reactors whenever diseases associated with streptococci became prevalent Lawrence (1952) in testing 472 persons having no apparent streptococcal infection found that only about 11 per cent failed to react at all but that only half of the subjects exhibited a well-established degree of sensitivity The sensitivity expressed was unequal to his testing materials suggesting elective sensitization to different bacillary constituents —vaccine cellular M substance and a par

tially purified culture filtrate rich in the enzymes streptokinase and streptodornase

Allergy to streptococci has been well studied in laboratory animals In natural infections with group C streptococci there is pronounced skin reactivity to streptococcal extracts in guinea pigs that are ill with epizootic lymphadenitis or are healthy carriers of the responsible microorganism (Moen 1936b) and there is reactivity in rabbits to extracts of their natural pathogen *Past cuniculicida* the organism causing snuffles (Hanger 1927)

Delayed type hypersensitivity can be established in rabbits with *viridans* streptococci by intracutaneous injection and by several other routes but not by intravenous injection Apparently in connection with the development of some focal tissue reaction the animals presented cutaneous ophthalmic and systemic hypersensitivity to the administration of living streptococci all being expressions of a delayed type of reaction unrelated to the amount or the type of circulating antibody and not transferable by serum

To relate further the mechanisms of streptococcal and tuberculin hypersensitiveness Moen (1936a) examined both sorts of sensitivity in parallel in tissue culture using explants of tuberculous tissues and explants of the spleen of guinea pigs infected with a natural streptococcal pathogen (group C hemolytic streptococci from guinea pig lymphadenitis) The presence of streptococcal extract led to a slowly developing specific toxic effect on the cells of streptococcus infected animals quite similar to but quantitatively less than that of tuberculin on tuberculin sensitive cultures The streptococcus sensitive cells exhibited more unequal gradations of sensitivity than were seen in tuberculin sensitive cultures some cells being killed rapidly others being only slightly inhibited Very much less evidence of persisting sensitivity was seen in subcultures of the streptococcus sensitive cells as compared with explants of tissues from tuberculous animals

As mentioned above Lawrence (1952) has reported transfer of streptococcal hypersensitivity from man to man by means of peripheral blood leukocytes

Pneumococcal Allergy Pneumococcal allergy has been studied in much the same way as has streptococcal hypersensitivity Deposition of vaccine in the skin of rabbits leads to a delayed type of skin reactivity toward pneumococcal vaccine or nucleoprotein and a delayed type of ocular reactivity (Julianelle 1930 Harley 1935 1937) the manifestation of reactivity to nucleoprotein is passively transferable by means of serum and apparently is of Arthus type whereas neither the allergy to vaccine nor the eye reaction is so transferable In contrast the injection of intact cocci by the intravenous route leads to the development of anticarbohydrate antibodies and to immediate type reactivity expressed toward the corresponding polysaccharide

During the course of pneumococcal pneumonia 2 types of specific skin reaction were observed (Tillett and Francis 1929) one being in response to the type specific capsular polysaccharide and appearing at the onset of convalescence consisting of an immediate reaction of urticarial type and the other elicited by species specific nucleoprotein and being of the tuberculin type A 3rd type of reaction can be produced by intradermal tests with somatic C polysaccharide of pneumococci during a limited period of the disease the reaction depends on a special protein (termed the C reactive protein) which appears as a consequence of many acute infections not only with the pneumococcus and happens to react with C polysaccharide even in vitro An analogous factor not capable of reacting directly with C polysaccharide appears also in animals during acute inflammatory responses viz to typhoid vaccine (Kushner and Kaplan 1961)

Skin Tests

To make any test practicable for diagnosis it is necessary to use relatively purified preparations to know the proper doses with respect both to tissue irritation and concentrations that will not cause focal reactions in positive reactors and to understand the specificity of the reaction It must also be known whether the material employed for skin testing can lead to active sensitization and vitiate future tests Even in the most

studied case tuberculosis investigation does not cease In instances in which both early and delayed reactions can be shown it is important to evaluate independently the significance of each type of reaction

In general when the method of testing is specific such tests have a significance similar to that of tuberculin a negative reaction in a healthy subject allays suspicion and a positive reaction denotes the occurrence of infection but gives no generally reliable indication of current activity A reaction of unusual size will require close scrutiny It is most informative when the skin reactivity is known to have been acquired recently One must recall furthermore that in advanced stages of all diseases including tuberculosis the skin may fail to react this condition is called anergy and has been considered to be a consequence of an exhaustion on the part of the tissue cells Also in intercurrent infection such as measles and chickenpox the tuberculous host temporarily may cease to give skin reactions to tuberculin Even a positive test which is specific may not always be of practical diagnostic value for example Sulzberger (1940) points out that interpretation of reactions to extract of Monilia (Oidiomycin) must be weighed against the well nigh universal exposure to various species of Monilia

In special cases delayed type hypersensitivity to proteins is encountered such as tetanus toxoid and diphtheria toxoid Consequently in performing the Schick test with diphtheria toxin—a test for the presence of neutralizing antibodies that avert the normal toxicity of the material for skin—a parallel test with heated toxin or with toxoid is used to detect the existence of sensitivity to the protein itself This tuberculin type of response representing the so-called false or pseudopositive Schick reaction lasts a day or so and then fades usually it can be differentiated from the positive Schick reaction in that *the true toxic effect appears slowly and* develops increasingly during the course of 4 or five days Both to purified diphtheria toxin and toxoid the tuberculin type of sensitivity occurs in about one fifth of young adults infrequently in children (Pappenheimer 1948) (In addition immediate type flare and wheal reactions occur in some individuals to these same constituents of diphtheria toxin and toxoid)

Tuberculosis Of the several varieties of tuberculoproteins and other mycobacterial products the preparation PPD is chiefly used in this country The 3 test strengths contain in 0 1 ml doses 0 02 0 2 and 5 0 mcg (1, 10 and 250 TU or international tuberculin units) termed respectively first test strength, intermediate strength and second test strength Other preparations of Seibert s from human tubercle bacilli are being evaluated currently some apparently being more reactive than standard PPD S (Vakilzadeh *et al*, 1962) (It should be mentioned that intradermal testing with a suspension of Choucroun s lipopolysaccharide PmKo gives more information at certain stages of the disease than does PPD see Kourilsky Choucroun and Gresland 1963) With the realization that persons reactive only to 250 TU of PPD S come from certain geographic areas (Edwards *et al* 1959) study has shown that tissue invasion in those localities occurs by strains of the atypical mycobacteria Tests made with PPD preparations of atypical mycobacterial strains place particular importance on PPD B prepared from the Battey (Group III) stain and to *PPD G* prepared from a scotochromogen (Group II) strain (reviewed by Youmans, 1963) Such tuberculins in standard doses of 5 TU (1 mcg) are especially useful in revealing infections with the atypical mycobacteria Avian PPD gives reactions in these particular patients also

Leprosy Lepromin an extract of heated human lepromatous nodules rich in bacillary bodies provokes skin reactions in patients with tuberculoid leprosy (cf Mitsuda 1936) (Lepromin produces cross reactions in tuberculin sensitive individuals) In addition to the initial tuberculin type reaction appearing within 2 days and termed the *Fernandez reaction the presence* of bacillary bodies can provoke nodular reactions starting by the 7th day and developing progressively in size for a month (Mitsuda reaction) It is interesting to note that the selective reactivity of lepromin for patients with tuberculoid but not lepromatous leprosy has

allowed positive identification of isolates growing in animal tissues as true *M leprae* (Shepard and Guinto 1963)

Brucellosis Skin reactions have been employed to detect present or past infection with Brucella both with Brucella vaccine and with an actively antigenic nucleoprotein extract Brucellergen (Huddleson 1943) The skin reactivity apearing in brucellosis of the guinea pig has been transferred by means of white cells (Metaxas Buhler 1952)

Tularemia Chemically treated (nitrous acid) vaccines have been injected intradermally as a diagnostic tool (Foshay 1940) During this disease as in pneumococcal pneumonia intradermal injection of *P tularensis* polysaccharide gives an immediate reaction of urticarial type Later when the patient s tissues contain an excess of polysaccharide intradermal tests with specific goat antipolysaccharide also produce an immediate type of reaction

Glanders The injection of *mallein* prepared from the causative agent of this disease *Actinobacillus mallei* can cause local focal systemic and ocular reactions as described for tuberculosis Cutaneous testing of infected horses and man has been practiced as well as of experimentally infected guinea pigs

Paratuberculosis of Cattle (Johne s Disease) The testing material is johnin a preparation made like tuberculin from the etiologic agent *Myco paratuberculosis* and variously purified dermal systemic and conjunctional reactions are encountered

Allergic Reactions to Fungal Materials Skin test materials are available to test for present or past infections with histoplasmosis coccidioidomycosis and blastomycosis all prepared as filtrates of culture medium (synthetic) which has supported growth of the fungi for several months in the mycelial phase In general tests for hypersensitivity are performed and interpreted as with the tuberculin tests Readings should be made both at 24 and 48 hours since significant reactions may vanish after the 1st day (Fiese 1958 Salvin 1959) In fungal diseases cutaneous anergy may develop as the lesions become widespread. The test materials—histoplasmin coccidioidin and blastomycin—are adjusted in potency to match reference standards and are diluted 1 100 for use in testing coccidioidin is diluted 1 1 000 for persons known to be highly sensitive

The active components in the skin test materials that produce delayed skin reactions are viewed as nitrogen-containing polysaccharides reportedly free of protein although one product prepared by Salvin and Smith (1959) was a protein-carbohydrate complex (Edwards Knight and Marcus 1961 see review by Salvin 1963) Polysaccharide seems to be the active principle in sporotrichin and paracoccidioidin also

The 3 test materials give varying degrees of cross reactions There is a particularly high degree of cross reactivity between histoplasmin and blastomycin and attempts have been made to eliminate the problem by extracting specific fractions Thus Dyson and Evans (1955) have suggested as a more specific test substance an alternative preparation separated by fractional alcoholic precipitation from culture supernatant of the yeast phase of *Blastomyces dermatitidis* Coccidioidin is more specific for reactions to it are found less frequently in histoplasmosis and blastomycotic infections than reactions with histoplasmin in coccidioidal infections (Smith *et al* 1949)

By reason of skin test surveys Edwards and Palmer (1963) hypothesize that in certain geographic areas that are free of coccidioidomycosis (e g Louisiana) the large number of feeble reactions encountered to histoplasmin probably represents cross reactivity reflecting infection with some new agent possibly another fungal agent

As in microbial hypersensitivity inhibition of macrophage migration—partial but specific—has been noted when histoplasmin was added to splenic explants of animals sensitized with *H capsulatum* (Carpenter 1963)

The coccidioidin hypersensitivity system has been studied recently for purposes of transfer of hypersensitivity (*vide infra*)

Allergic Reactions to Viral Materials Evidence of hypersensitiveness of the delayed type was observed unknowingly by Jenner in 1798 with the virus of cowpox individuals

rendered immune by inoculation with cowpox virus later responded to this or the closely related smallpox virus with a small local redness that appeared within 48 to 72 hours and then faded quickly This manner of response was interpreted as an allergy by von Pirquet and Schick in 1903 the role of hypersensitivity was convincingly demonstrated when Hooker (1929) injected heat inactivated virus into the skin of cowpox immunized individuals

The Frei test (originally an injection of diluted and heat sterilized pus from the lesion later of infected mouse brain) is now performed with antigen obtained from chick-embryo cultures A skin test betokening past infection with mumps virus has been developed by Enders *et al* (1945 1946) for the assessment of immunity Newer test preparations have been made of viral material grown in the allantoic fluid of embryonated eggs (Henle *et al* 1951)

Allergy in Parasitic Infestations In contrast with the above observations the form of allergic response that has received chief consideration in parasitic helminth infestations—for example schistosomiasis echinococcus disease filariasis trichiniasis and ascaris infestation—has been the immediate reactions of the wheal and-erythema type found when the skin of the host is tested with extracts of the body substance of the same or related parasites usually antibodies can be demonstrated in the serum by serologic methods at the same time Asthma and rhinitis are sometimes elicited upon exposure to the specific agents While there is often an early reaction to hydatid fluid in echinococcus infestation it appears that the delayed type or *Casoni reaction* should be given chief diagnostic interpretation

In protozoan infestations skin tests have been less useful The only instance to be mentioned is leishmaniasis in which a tuberculin like reaction has been observed in skin tests made with an extract of cultured Leishmania

Even as an aftermath of sensitization by insect bites delayed allergic reactions have been demonstrated (Benson 1936) independently of early reactions (and corresponding reagins) which occur at times both varieties may be seen in the same individual

THE ADJUVANT EFFECT OF TUBERCLE BACILLI AUTO-ALLERGIC DISEASES

Special properties of *Myco tuberculosis* came to light when Dienes (1929) showed that the injection of protein antigens into a tuberculous focus led to a delayed type of hypersensitivity directed against the protein as well as the expected appearance of circulating antibody The induced tuberculin type hypersensitiveness to egg protein as Burnet (1948) has said therefore seems to be definitely related to the placing of the antigen in an inflammatory area in which histiocytes and lymphocytes predominate

Following the discovery by French workers that the sensitizing property of killed mycobacteria is greatly enhanced in the presence of hydrocarbons Freund and McDermott (1942) imitated Dienes injection of protein into a tuberculous focus by blending horse serum and an emulsifier in paraffin oil containing killed tubercle bacilli and injecting the water in-oil emulsion Probably owing to the type of cellular response evoked by the liquid hydrocarbon and the mycobacterial substance an intense cutaneous reactivity to horse serum of delayed type resulted At the same time the output of circulating antibody became exaggerated and was sustained for many months

Therefore in animals so prepared a high degree of Arthus type reactivity is superimposed on the original Dienes effect Reference to either or both of these effects is variously intended when the term adjuvant effect of killed mycobacteria is used but it is necessary to distinguish between the effects due to the presence of mycobacteria and the effectiveness of antigen dispersed in hydrocarbon *without* the incorporation of mycobacteria or special mycobacterial wax So far as the concentration of circulating antibody is at issue the mycobacteria often can be omitted from the emulsion but the direc tive effect of the mycobacteria is needed in order to secure certain of the delayed type allergenic effects

When brain substance was incorporated in the Freund adjuvant it was found that a fatal demyelinating disease was induced in monkeys with disseminated lesions in brain and cord (Morgan 1946 Kabat Wolf and Bezer 1946) The effect was secured only

when mycobacteria were included in the emulsion The disease currently termed experimental allergic encephalomyelitis or EAE has been studied intensively in laboratory animals particularly in guinea pigs rabbits rats and certain strains of mice it has been viewed as a possible laboratory prototype of multiple sclerosis (see Kolb 1950) That the mechanism is independent of any subtle intraspecies antigenicity of brain substance has been nicely shown by Kabat *et al* (1949) who induced the condition in monkeys in response to a portion of their own brain substance removed in a prior operation The active material in brain resides chiefly in the white matter and has been isolated in several forms differing in their effectiveness in the various species of laboratory animals—proteolipid basic protein and most recently a dialyzable encephalitogen (Robertson *et al* 1962)

Delayed type reactions to brain are demonstrable by intradermal testing under appropriate conditions Thus Waksman and Morrison (1951) found dermal and corneal reactivity in tests with rabbit brain after homologous brain had been injected intradermally in Freund type adjuvant in order to prepare rabbits for EAE and Alvord and colleagues recently have found a skin reaction in guinea pigs to the encephalitogenic basic protein of homologous brain Such reactivity at 10 days had predictive value for early onset of EAE

The event of EAE can be deviated by injecting either brain or mycobacteria some days before administration of brain emulsified with mycobacteria apparently an initial production of antibrain antibodies effectively diverts the sensitization process as does prior sensitization to mycobacteria Thus Paterson and Harwin (1963) have found that injections of antibrain serum (19S antibodies) before sensitization can suppress development of EAE in rats Also the use of 6 mercaptopurine which suppresses immunologic activity will postpone the onset of EAE (Hoyer Good and Condie 1962)

Iso antibodies to brain substance are found irregularly one (19S) fixing complement with brain extracts and another type (with complement) being cytotoxic for cultured myelin and glial cells Serum does not transfer the condition to normal animals (cf Waksman and Morrison 1951) but transfer between rats and between isologous guinea pigs has been effected by means of lymph node cells (Paterson 1960 Paterson and Didakow 1961 Paterson and Bell 1962 Stone 1961) Rats developing EAE after cellular transfer also develop cytotoxic antibody but its relation to the lesions is not demonstrated However rabbits with induced EAE possess specific immunoglobulins that localize specifically in the myelin sheaths and glial cell membranes of cultured rat cerebellum causing marked demyelination within a few hours (Appel and Bornstein 1964)

An allergic neuritis has been shown to occur as another distinct entity when peripheral (sciatic) nerve is used instead of brain suggesting immunologic differences in myelins from the 2 sources (Waksman and Adams 1955 1956) Transferred recently to a tissue culture system of trigeminal ganglia the process of demyelinization has been observed to occur within 3 days when specifically competent lymph node cells were added to the culture and only infrequently when serum of the cell donors was used (Winkler 1964)

If testicular tissue instead of brain is incorporated in the emulsion another but non fatal iso allergic condition arises namely a marked degeneration of sperm cells from spermatogonia to the mature sperm this condition can be initiated by injection of material from one of the animal s own testicles removed beforehand (Voisin *et al* 1951 Freund *et al* 1953 1955) The active antigen is heat stable and contains polysaccharide or glycoprotein

With use of thyroid tissue likewise incorporated in mycobacterial adjuvant even auto allergic thyroiditis could be demonstrated by Witebsky and co workers rabbits being sensitized with portions of their own thyroid (cf Terplan *et al* 1960) Studied in a histocompatible strain of guinea pigs a chronic primarily lymphocytic disease was found to persist for 2 years after its peak severity at 2 months (Lerner and McMaster 1964) Delayed type reactions to thyroid were found at 5 to 7 days before onset of the disease and antithyroid antibody ap

rendered immune by inoculation with cowpox virus later responded to this or the closely related smallpox virus with a small local redness that appeared within 48 to 72 hours and then faded quickly This manner of response was interpreted as an allergy by von Pirquet and Schick in 1903 the role of hypersensitivity was convincingly demonstrated when Hooker (1929) injected heat inactivated virus into the skin of cowpox immunized individuals

The Frei test (originally an injection of diluted and heat sterilized pus from the lesion later of infected mouse brain) is now performed with antigen obtained from chick-embryo cultures A skin test betokening past infection with mumps virus has been developed by Enders *et al* (1945 1946) for the assessment of immunity Newer test preparations have been made of viral material grown in the allantoic fluid of embryonated eggs (Henle *et al* 1951)

Allergy in Parasitic Infestations In contrast with the above observations the form of allergic response that has received chief consideration in parasitic helminth infestations—for example schistosomiasis echinococcus disease filariasis trichiniasis and ascaris infestation—has been the immediate reactions of the wheal and erythema type found when the skin of the host is tested with extracts of the body substance of the same or related parasites usually antibodies can be demonstrated in the serum by serologic methods at the same time Asthma and rhinitis are sometimes elicited upon exposure to the specific agents While there is often an early reaction to hydatid fluid in echinococcus infestation it appears that the delayed type or *Casoni reaction* should be given chief diagnostic interpretation

In protozoan infestations skin tests have been less useful The only instance to be mentioned is leishmaniasis in which a tuberculin like reaction has been observed in skin tests made with an extract of cultured Leishmania

Even as an aftermath of sensitization by insect bites delayed allergic reactions have been demonstrated (Benson 1936) independently of early reactions (and corresponding reagins) which occur at times both varieties may be seen in the same individual

The Adjuvant Effect of Tubercle Bacilli ' Auto-allergic Diseases

Special properties of *Myco tuberculosis* came to light when Dienes (1929) showed that the injection of protein antigens into a tuberculous focus led to a delayed type of hypersensitivity directed against the protein as well as the expected appearance of circulating antibody The induced tuberculin type hypersensitiveness to egg protein as Burnet (1948) has said therefore seems to be definitely related to the placing of the antigen in an inflammatory area in which histiocytes and lymphocytes predominate"

Following the discovery by French workers that the sensitizing property of killed mycobacteria is greatly enhanced in the presence of hydrocarbons Freund and McDermott (1942) imitated Dienes injection of protein into a tuberculous focus by blending horse serum and an emulsifier in paraffin oil containing killed tubercle bacilli and injecting the water in-oil emulsion Probably owing to the type of cellular response evoked by the liquid hydrocarbon and the mycobacterial substance an intense cutaneous reactivity to horse serum of delayed type resulted At the same time the output of circulating antibody became exaggerated and was sustained for many months

Therefore in animals so prepared a high degree of Arthus type reactivity is superimposed on the original Dienes effect Reference to either or both of these effects is variously intended when the term adjuvant effect of killed mycobacteria is used but it is necessary to distinguish between the effects due to the presence of mycobacteria and the effectiveness of antigen dispersed in hydrocarbon *without* the incorporation of mycobacteria or special mycobacterial wax So far as the concentration of circulating antibody is at issue the mycobacteria often can be omitted from the emulsion but the directive effect of the mycobacteria is needed in order to secure certain of the delayed type allergenic effects

When brain substance was incorporated in the Freund adjuvant it was found that a fatal demyelinating disease was induced in monkeys with disseminated lesions in brain and cord (Morgan 1946 Kabat Wolf and Bezer 1946) The effect was secured only

as a flare in previously injected sites owing to a reaction with remaining traces of the sensitizing complex The full degree of sensitivity is best demonstrated by applying the same material (usually dissolved in a suitable vehicle) to a fresh area of the skin or by injecting intracutaneously either the incitant or an artificial conjugate antigen" made by joining the incitant to an appropriate soluble protein

The identification of sensitizing chemicals as those which can combine with proteins was demonstrated in the case of chloro and nitro-substituted benzenes (Landsteiner and Jacobs 1936) and conversely sensitive animals can be provoked to react by other chemically related compounds only when the latter can themselves combine with proteins (Eisen *et al* 1952) However not all classes of sensitizing substances exhibit so clear a basis for combination with proteins and alteration in vivo prior to combination must be assumed

Study in guinea pigs again points clearly to an altered behavior of lymphoid cells altered behavior of macrophages and a stimulus to form immunoglobulins and it emphasizes the cellular basis of contact sensitivity Upon transfer of living mononuclear cells the delayed type of dermal sensitivity not transferable with serum is imposed on normal guinea pigs exactly as in the case of tuberculin hypersensitivity (Landsteiner and Chase 1942 Haxthausen 1947 Nilzen 1952 Seebohm Tremaine and Jeter 1954) For this manner of sensitization Mitchison has introduced the term adoptive transfer The general histology of contact reactions after cellular transfer has been studied by deWeck and Brun (1956) With use of marker technics mentioned previously donor cells are found in reacting test sites of the recipient animal in small ratio to host mononuclear cells The chief question concerns the attraction of donated cells to test sites as to whether the ratio of donor to host cells differs in test sites from that in lymphoid tissue or the circulation Some workers have not found an elective concentration of labeled cells in cutaneous test sites greater than in the organs (Hamilton and Chase 1962 McCluskey *et al* 1963) but others have found specific accumulations (Najarian and Feldman 1961 1963 Kay and Rieke 1963) In respect to their findings Najarian and Feldman (1963) are inclined to view the ratios found as representing preferential *retention* of labeled competent cells in specific test sites rather than specific attraction

In man it has proved to be unexpectedly difficult to transfer contact type sensitivity with cells However experimental sensitivity to 2 4-dinitrochlorobenzene seems to have been so transferred into patients with hypogammaglobulinemia (Good *et al* 1957 1962) and sensitivity to dinitrochlorobenzene paranitrosodimethylaniline and perhaps poison ivy also (Epstein and Kligman 1957) If so the mode of sensitivity in man would be established In this connection one will recall the already mentioned experiment of Haxthausen in transplanting skin between identical twins one of whom had been sensitized with dinitrochlorobenzene When a satisfactory operational procedure is devised for this type of study in man one may expect positive results rather than negative or borderline instances of transfer that have been reported (Baer and Sulzberger 1952 Baer *et al* 1952 Harber and Baer 1961) Recent studies on exudates and blister fluids and cells adhering to cover slip windows at the site of specific reactions have shown a surprising richness in the types of white blood cells that are associated with passive transfer (Nexmand 1949 1950 Baer and Yanowitz 1952 Braunsteiner *et al* 1958 cf Fellner 1919)

In experimental sensitization with simple chemical allergens not only delayed-type hypersensitivity to contact with the chemical arises but immunoglobulins are synthesized as well (Chase 1947) these probably being chiefly of the 7Sγ_1 variety (see page 244) Allergic conversion precedes the appearance of antibody the interval shortening as sensitizing applications are increased in number For demonstration of the antibody usually by PCA the preparation of soluble haptene protein conjugates is required systemic anaphylactic shock often can be shown also

When cellular transfer is made from animals that possess delayed type hypersensitivity and are actively synthesizing circulating immunoglobulins the transferred cells can

peared slightly later By chemical modification of thyroglobulin that reduces the amount of circulating antibody, Miescher *et al* (1961) concluded likewise that delayed type hypersensitivity is the basis of the tissue damage rather than antibody

Auto immune nephrosis occurs when rats are sensitized by repeated injections of kidney extract with mycobacterial adjuvant and the disease can be transferred by means of lymph node cells (Hess Ashworth and Ziff 1962)

Contact Dermatitis*

The most common route of sensitization to natural products and defined chemical substances is the percutaneous one involving direct contact with the skin Existing irritations in the skin the kind of perspiration the chemical properties of the sensitizing material and the intensity of exposure are prime factors in sensitization In addition inherited factors influencing the degree of susceptibility such as are proved to occur in animals almost certainly exist in man Most frequently encountered by far is the delayed type of reaction with manifestations ranging from macules to frank epithelial injury and exfoliative dermatitis but reagins have been detected now and then and doubtless stimuli arise for synthesis of the more usual types of immunoglobulins as well

Inciting agents or contactants range from water soluble to fat soluble materials and can arise for example through the action of acidic perspiration on nickel-plated jewelry One widespread agent is the catechol derivative of the poison ivy plant urushiol which causes the allergy known as poison ivy dermatitis with frequent presentment of separation of the epithelial layer and formation of bullae Mild forms of contact dermatitis naturally can be mimicked by temporary superficial inflammations

The causative agents, not antigens as such appear to acquire antigenic capacity by combining with the tissues of the host (either directly or after some intermediary chemical alteration in vivo) as conjugated haptene protein structures analogous to the artificial conjugated antigens of Landsteiner Such haptene protein structures are believed to incite sensitization and to elicit subsequent reactions whenever the same or a chemically related substance presents itself by the proper route

Experimental investigation may be said to date from 1896 when Jadassohn first published his careful observations and introduced the patch test as a diagnostic procedure in the study of contact dermatitis The idea that such allergies represented individual and innate idiosyncrasies became untenable when Bloch and Steiner-Wourlisch (1926) pointed out that any individual could be rendered sensitive to the primrose plant (*Primula obconica*) if one simply used a concentrated extract of *Primula* leaves and a sufficient number of applications Some persons became sensitive after 1 application whereas others required several treatments and evidently the role played by heredity was reflected in this variable sensitivity The same workers next showed (1930) that guinea pigs as well could be sensitized to *Primula* and Mayer (1931) demonstrated that like human beings guinea pigs could be made sensitive to paraphenylenediamine a compound often used in the dyeing of furs The way was now open for animal experimentation for the manifestations of dermatitis in man and in sensitized guinea pigs were analogous even if not identical

Experimentation in guinea pigs has proceeded with use of 2 4 dinitrochlorobenzene picryl chloride *p* nitrosodimethylaniline *p* phenylenediamine 2 phenyl 4 ethoxymethylene 5-oxazolone substituted benzoyl and benzyl chlorides acid anhydrides Salvarsan urushiol and so on most being proved to be sensitizers of man also In both species sensitization is accomplished by repeated applications made on or into the skin and it may be necessary to provide a previously irritated cutaneous area for the treatments These technics sensitize the skin generally though in man there is some evidence for a slight delay before areas remote from the site of application acquire their sensitivity The *sensitivity arises usually in 5 to 10 days* and often is seen first on the 7th or the 8th day

* The reader is referred to Sulzberger (1940) Landsteiner (1945) Carr (1954) and Jadassohn (1932) for reviews which deal with historic and theoretic aspects

yet been evolved and except for spontaneous recession the sensitivity soon returns as is true in all other types of allergic manifestations Thus the degree of dinitrochlorobenzene sensitivity in animals could be lowered for only a short period by giving very large amounts of the allergen intravenously (Frey and Geleick 1962) For use in special studies it may be mentioned that guinea pigs can be *prevented* from undergoing specific sensitization to certain simple chemicals by certain elective experiences induced with the chemical before attempting experimental sensitization (intravenous injection of arsphenamine Sulzberger feeding of fat soluble allergenic chemicals Chase)

In man immediate type flare and wheal reactions to drugs have been found in several instances (Salvarsan formaldehyde phthalic anhydride chloramine T sulfathiazole and sulfadiazine) and often are accompanied by demonstrable reagins it is evident that these incitants which can give early type reactions would belong largely in the category of the more reactive compounds capable of rapid coupling to form haptene protein conjugates It may well be that as in the case of immunoglobulins in guinea pigs sensitized with chemicals these reagins may occur more commonly than has been recognized and that their detection by skin test may wait upon the use of suitable haptene-carrier conjugates For example using succinylated polylysine as a nonprotein (and nonantigenic) carrier of dinitrophenyl groupings Parker Kern and Eisen (1962) elicited flare and wheal reactions in a sensitive human subject as readily as with dinitrophenylated protein

In order to search for nonreaginic antibodies that may be present even in low concentrations in human beings exhibiting delayed hypersensitivity many novel methods have been proposed These deal chiefly with the use of allergen-coupled erythrocytes to detect antibody either by direct agglutination or by indirect tests for adsorption of immunoglobulin (cf Coombs Mynors and Weber 1950 Coombs and Fiset 1954) that would be similar in principle to the Middlebrook Dubos or the Boyden tests for the detection of antibodies in tuberculosis With certain very simple chemical allergens direct coupling to erythrocytes has been made (Johnson 1962 Bullock and Kantor 1964) these proving useful in animal experimentation With many allergens of man however it may not be possible to couple to protein without enslaving the immunologically determinant sites of the allergens

Delayed Sensitivity to Proteins

Seen only transiently in man and there termed the Jones Mote phenomenon delayed sensitivity to proteins has been studied extensively in laboratory animals After a single intradermal sensitizing injection of protein reinjection between the 3rd and the 5th days reveals a delayed type response initiated by small mononuclear cells but thereafter immunoglobulin appears and the delayed sensitivity is lost to view The time at which masking antibody will appear can be postponed by sensitizing with only small amounts of protein (3 to 30 mcg) or with protein precipitated by specific antibody (Uhr *et al* 1957) or with protein altered chemically by heavy coupling to haptenes In most instances the sensitizing procedure primes the immunologic apparatus silently so that a secondary response is evoked by the first subsequent skin test therefore these studies of delayed sensitivity are carried out usually with single tests made around the 8th to the 10th days The subject is reviewed in detail by Gell and Benacerraf (1961) and by Salvin (1962)

Examples of the experimental sensitization of man to proteins have been provided by the so called one shot treatment of allergic patients with allergens incorporated in mineral oil The inclusion in such emulsions of allergens to which the patient did *not* possess a specific hypersensitivity (wheal and flare type) has been found to induce long sustained delayed type reactions sometimes with ulceration (Feinberg *et al* 1960 Becker *et al* 1961)

Homograft Rejection

Skin and organ homografts placed in genetically unselected individuals are rejected regularly within 10 days to 3 weeks but not when donor and recipient are syngenic (identical twins highly inbred strains of mice and guinea pigs) The manner of

give rise to synthesis of antibody in the recipient as well as delayed hypersensitivity (Chase 1951) several days are required for detectable synthesis of antibody and the process stops at the time of the rejection of the donated cells The cellular transfers of delayed type hypersensitivity and of antibody synthesis are independent events indeed if donors have been stimulated with such antigens as bacterial extracts and diphtheric toxoid antibody synthesis can occur following cellular transfer (Harris and Harris 1951 Wager and Chase 1952)

The mechanism underlying drug sensitization appears to be involved intimately with the antibody producing system That in the establishment of delayed type sensitivities one is dealing with some part of the antibody-producing mechanism seems to follow also from some other observations First dermal sensitivity of the delayed type can be induced by an insoluble complex antigen (made of the chemical coupled to erythrocyte stromata) when it is used along with the Freund adjuvant (Landsteiner and Chase 1941 cf Chase 1954) Second when one feeds certain allergenic chemicals to non-sensitized animals there is induced a state of specifically depressed receptivity involving both the acquisition of delayed type *dermal sensitivity and the production of antibody* The animal acquires resistance to a subsequent dermal sensitization with this chemical and upon stimulation with conjugated homologous antigens bearing the same immunologically determinant structure there is pronounced depression in synthesis of corresponding circulating antibodies (see p 294) Again administration of methotrexate (aminomethylpteroylglutamic acid) which depresses the immunologic apparatus was found to block development of contact sensitivity and the primary antibody response (Friedman Buckler and Baron 1961)

Although sensitization as induced by percutaneous or intradermal application of chemical allergens shows specificity within the bounds set by their structures closer examination reveals that specificity is not related solely to the haptenic group that couples to self protein for adjacent portions of the carrier constitute part of the sensitizing structure (cf Benacerraf and Gell 1959 Gell and Benacerraf 1961a 1962b Salvin and Smith 1960 Benacerraf and Levine, 1962 Gell and Silverstein 1962 Leskowitz, 1963) In many such studies unfortunately sensitization has been effected with adjuvant incorporating highly coupled haptene protein conjugates, enough so to mask the role of the specific haptene moiety

In parallel with tuberculin hypersensitivity the macrophages of guinea pigs sensitized with simple chemical allergens display inhibition of migration in vitro when specific soluble haptene protein conjugates are added such as picrylated bovine gamma globulin in picryl chloride sensitive animals (Carpenter 1963 David *et al* 1964 Stinebring Axelrod and Trakatellis 1963) Again the role played by the carrier protein looms large

In studying the cellular changes occurring within auricular nodes chemical allergens being applied to the ear Turk and Stone (1963) found a marked increase of large pyroninophilic cells on the 3rd and the 4th days exactly at the time of incipient contact sensitivity Sensitivity ascended during the following 4 days as these large cells declined in number As postulated by Gowans (1962) the evidence was that the large pyroninophilic cells arose from small lym*phocytes and in turn gave rise to* immunologically competent small lymphocytes Cellular transfer of contact type sensitivity was regularly successful by the 5th day whole lymph node slices being used The relationship of the observed cellular changes to antibody synthesis on the one hand and on the other hand to development of cells effective in transfer of contact sensitivity is not known Processes known to interfere with the immunologic apparatus—specific tolerance cyclophosphamide—blocked the cellular changes although methotrexate permitted large cells to develop but still prevented sensitization

Finally it may be said that attempts at desensitization in contact dermatitis in man have met with limited success Some cases recede spontaneously a few others have been benefited by subcutaneous injection of the incitant in an oil vehicle (Caulfield 1936) or by cautious ingestion (Park 1944 Stevens 1945) A useful method has not

Converse and Tillett (1960) studied transfer factor (see p 277) prepared from lymphocytes of persons actively rejecting skin homografts (As mentioned previously such investigations are now possible only in man) The plan consisted in the transfer of acquired hypersensitivity transferred from an individual rejecting a particular skin to an individual newly grafted with the same skin and in the finding of accelerated rejection as compared with an indifferent skin graft Preparations made from the leukocytes of 3 persons who had rejected skin 4 times in succession caused specific accelerated rejection when injected into the intended recipients 8 days before or 3 days after grafting preparations from 3 individuals who had rejected a skin only twice were weaker and caused rejection only if infiltrated around the graft after vascularization on the 3rd day The factor in the lymphocytes was lost quickly and effective preparations could be secured only at the height of the rejection

As Stetson and Demopoulos (1958) showed circulating immunoglobulin is entirely adequate to ensure rejection of newly placed skin grafts but is of little effect on well established grafts serum complement seems to be required for the action of such antibody Other evidence supports this view as Gorer (1960) and Amos (1962) have emphasized the homograft reaction is complex and the basis of rejection may include in varying measure both delayed type hypersensitivity and humoral antibodies Demonstration that humoral antibody occurs in sufficient concentration to reject first set homografts has seldom been offered Homograft rejection was interpreted by Najarian and Feldman (1962 1963a b) to depend solely on an antibody mechanism labeled spleen and lymph node cells transferred from mice or guinea pigs that were stimulated by both skin graft and injection of spleen cells did not appear in the recipient s test graft although rejection occurred Finally a globulin-containing extract of the transfer cells was shown to effect rejection directly and in small amount Whether this is the sole mode of homograft rejection remains moot since antibody can be found in spleen cells of animals actively synthesizing it Yet Prendergast (1964) found that substantial numbers of labeled cells were present within all of 4 skin homografts during their rejection although the labeled cells arose only within one node that drained one of the homografts And indeed one finds a heavy infiltration of small lymphocytes in first set homografts

The participation of lymphocytes in both delayed type hypersensitivity and in events leading to antibody formation emphasizes the difficulty in separating the 2 functions Gowans McGregor Cowen and Ford (1962) and Gowans (1962) have shown impairment of primary antibody formation in rats by thoracic duct drainage and restoration by return of lymphocytes to the circulation a finding quite in accord with the role of lymphocytes in antibody production following stimulation with RNA from macrophages that had been incubated with antigen (Fishman and Adler 1963) Also Gowans *et al* studied transformation of rat small lymphocytes stimulated by placement in an alien host the small lymphocytes went to the spleen became large pyroninophilic cells and finally produced further small lymphocytes This sequence of changes occurs in the graft versus host reaction as well as in skin homograft rejection

The graft versus host phenomenon following cellular transfer implies that instead of expected homograft rejection transferred cells sometimes can respond to antigens of the recipient animal and affect the latter s well being (cf Simonsen 1962) This effect —termed homologous disease or runt disease or wasting disease—depends on the relative impact of antigenic stimulation and it varies considerably according to the choice of donor and the recipient strains e g among inbred mouse strains Homologous disease in the adult rat shows a great variety of allergic inflammations the reaction leading to dermatitis of host skin and rejection of autografts even while homografts are becoming established free of dermatitis (Stastny Stembridge and Ziff 1963)

In the area of allergic encephalomyelitis (EAE) rat lymphocytes taken on the 7th to the 11th days after the sensitizing injection of brain (in mycobacterial adjuvant) were found to cause destruction of glial elements of cultured puppy brain first ag

initial rejection and the speedier rejection of a later identical graft point to immunologic mechanisms The manner of rejection of a first set graft shows similarities with tuberculin type allergy as has been outlined by Lawrence (1957) and emphasized by experimental studies in animals (Medawar, 1958, Brent Brown, and Medawar 1959 Billingham Silvers and Wilson 1963) Second set grafts from the same donor are rejected more quickly Sooner or later attempts to regraft meet with failure to vascularize even briefly, as witnessed by the telltale white graft This final stage is attributed to interference by circulating antibody passive transfer of selected sera will duplicate the effect (Stetson and Demopoulos 1958) Sufficient antibody indeed can be directly damaging for first implanted cells (Siskind and Thomas, 1959 Gorer and Boyse 1959) These points of view—emphasis on delayed type hypersensitivity vs a role of immuno globulins—will be discussed in turn

Not only the lymphocyte but also the macrophage assumes a new role after the onset of sensitization The rejection of incompatible tumors by mice has emphasized the role of the macrophage phagocytosis being often prominent Monocytes transferred after such rejection can protect other mice from successful implantation even when washed free of iso antibody (Old *et al*, 1963) Another interesting example is the acute allogenic disease studied by Granger Weiser and Holmes (1963) when an ascites tumor indigenous to strain A mice is used to sensitize C57Bl mice the latters macrophages *not* lymphocytes are found to be capable of killing normal strain A mice within 40 hours by attacking primarily the capsule of the pancreas humoral antibody *not* being detectable

Consonant with the interpretation that delayed type hypersensitivity underlies first set rejections are experimental studies in animals showing similarities in the time of onset of the reaction the histology of the graft bed a failure to transfer with serum and especially a role of lymphoid cells in inciting rejection of tolerated grafts the cells being transferred from graft sensitized individuals (cf Billingham Silvers and Wilson 1963) Moreover such graft sensitized guinea pigs exhibit a delayed type sensitivity toward extracts of the donor s tissues and yield lymphoid cells that produce local hypersensitivity reactions when injected into the donor s skin (Brent Brown and Medawar 1962) Still further evidence for the role of delayed type hypersensitivity is offered in the rejection of skin homografts by fetal lambs approaching delivery although an ability to respond to antigens is developing slowly they reject skin regularly without the presence of discernible antibody (Schinkel and Ferguson 1953 Silverstein Prendergast and Kraner 1963)

Other evidence has been cited against a major role of humoral antibody in graft rejection When alien homologous cells are placed within a noncompatible host as target tissue but in chambers faced by special permeable (Millipore) membranes the cells survive (Algire *et al* 1954, 1957 Weaver *et al* 1955 Billingham and Silvers 1963, Billingham Silvers and Wilson 1963) However destruction ensues when immunologically competent cells are introduced into the chamber damage extending both to target cells and lymphoid cells (Weaver *et al* 1955) Many attempts to duplicate this result in vitro failed finally Rosenau and Moon (1961 1962 cf Rosenau 1963) used specifically competent lymphocytes in high ratio to target cells and indeed found cytolysis of mouse L-cell fibroblasts During the 1st day the slow attachment of perhaps 5 per cent of the lymphocytes was seen whereas lysis was most rapid between 36 and 48 hours Cytolysis of this type occurred without addition of serum complement In contrast humoral cytotoxic antibodies required a supplementary source of complement to effect lysis of such cells In similar exposures of cultured thyroid cells to competent lymphocytes Rose *et al* (1963) found thyroid cells to round up to retract and to cease growth yet the effect could be duplicated when lymphocytes of nonthyroid itis provenance were used in sufficiently great numbers Neither donors serum nor cell sap of the competent lymphocytes produced any effect on the cultured cells

Seeking in another way to demonstrate that homograft rejection depends on delayed type hypersensitivity Lawrence Rapaport

and Moon and only 5 to 35 per cent of lymphocytes in studies made by others were stimulated by tuberculin to synthesize gamma globulin in vitro (Pearmain *et al* and Hirschhorn *et al*) despite the competency of all the lymphocytes to form gamma globulin under the stimulus of bean leukoagglutinin (p 277) Yet it should be emphasized again that monocytes acquire new properties in consequence of sensitization as is shown well by in vitro inhibition of migration by exposure to the allergen and by the sequences seen in experimental listeriosis (p 278)

It seems curious that in man the transfer of microbial hypersensitivities is accomplished with so few cells as 0 15 ml moist volume and the hypersensitivity persists for so long (cf Lawrence 1960 Good Kelly Rotstein and Varco 1962) whereas in animals the hypersensitivity appears to be a function of survival of the transferred cells The easy separation of transfer factor from this small number of cells and the demonstration of dialyzability and small molecular weight should shortly increase our understanding of delayed type hypersensitivity in a way seemingly not possible by animal experiments

In an endeavor to rule out re excitation of existing but latent hypersensitivities—the constant hazard in dealing with microbial hypersensitivities—Rapaport Lawrence Millar Pappagianis and Smith (1960) studied transfer of coccidioidin hypersensitivity in man using as recipients persons far removed from an endemic area of coccidioidomycosis Transfer was successful reactions occurring to tests made 6 to 14 days later Control leukocytes from the single negative individual used gave only 1 moderate transfer among 9 recipients injected An extensive series of transfers with frozen human cells was made by Jensen Patnode Townsley and Cummings (1962) from persons variously sensitive to special tuberculins (PPD S PPD Battey and PPD Avian) recipients being tested on days 2 7 and 30 Transfers were multiple being positive in 70 per cent of 26 trials but positive only in 30 per cent toward PPD S In 6 instances sensitivity appeared to tuberculins that were not reactive in the donors and 1 negative control donor appeared to transfer reactivity to PPD B and PPD A Histoplasmin sensitivity proved to be difficult to transfer in this way even from good reactors

It has been noted that the special waxy substance of mycobacteria possesses a remarkable directive effect in inducing delayed type hypersensitivity to tuberculin and to other proteins or haptene protein complexes deliberately injected with it (cf White in Shaffer *et al* 1958) The directive effect may well be the attraction of cellular types such as monocytes and cells of the lymphatic series and the resultant formation of a local granulomatous response In addition the use of mycobacterial wax as adjuvant is accompanied by a widespread proliferation of plasma cell elements and an increased amount of antibody (White Coons and Connolly 1955) In the guinea pig indeed the effect of mycobacteria on antibody formation appears to be electively to induce synthesis of $7S_{\gamma}$ antibody (White *et al* 1963) Benacerraf *et al* 1963)

For the special case of chemical allergens Mayer (1957) has suggested that fibroid proteins such as collagen rather than soluble proteins may be the necessary carrier for the coupling that leads to delayed type hypersensitivity Mayer s evidence rests on his finding that procollagen may be substituted for mycobacteria or mycobacterial wax in a *special procedure of sensitizing the skin* by injecting a chemical allergen intraperitoneally and allowing coupling in situ The conclusion that the usual role of mycobacteria is to allow local accumulation of collagen as in the peritoneal cavity requires further examination

The hypothesis of cell bound antibody has been offered to explain the injury done by tuberculin to monocytes of the tuberculous host and by extension has been applied to lymphocytes which have been regarded as the prototypic cell in delayed type hypersensitivity The closest approach to cell bound antibody is the specific nonimmunoglobulin transfer factor of Pappenheimer and Lawrence However Bloom *et al* (1964) have concluded from metabolic alterations secured with Mitomycin C that transferred guinea pig cells must continue to metabolize in the new host in order to produce contact reactions Protein synthesis is suggested also

glutinating on to the glial elements and then largely disappearing within 4 days destruction of the cells occurred within 6 days The serum contained antibody that was absorbable by nonsensitized lymphocytes which then showed weaker contactual agglutination onto glial elements and apparently caused some destruction of the latter (Koprowski and Fernandes 1962)

The opposite of homograft rejection homograft tolerance, remains under active study because of its theoretic implications (cf Brent and Gowland 1963) The artifice of establishing tolerance through neonatal experience with cellular antigens (white cells of spleen peripheral blood lymph nodes) was established by the brilliant experiments of Medawar Billingham and Brent the subject has been reviewed in extenso by Brent (1958) and Hašek *et al* (1961) Tolerance can be established in certain cases in older animals by administering during the days of first contact with foreign tissue antimetabolites (p 294) that suppress the functioning of the immunologic apparatus Tolerance can be abolished by injecting isogenic cells either normal or with more prompt rejection those having a specifically acquired competence against the graft (Billingham Silvers and Wilson 1963)

Theoretical Considerations of *Delayed Type Hypersensitivity*

As we have seen the delayed type of hypersensitivity is associated in some way with alterations in cells lymphocytes and macrophages especially and with antigenic stimuli that lead in a measure to synthesis of circulating immunoglobulins Some unifying principles must underlie the delayed type of hypersensitivities that are apparent after microbial invasion after application of contactant chemicals after primary intradermal injections of soluble proteins and probably after the placing of homografts It has been suggested that delayed type hypersensitivity is the earliest and an immature stage in antibody formation directed against large surface areas of the inciting material in contrast with the production of mature antibody which recognizes limited areas or surface patches of antigen (Salvin and Smith 1960) Because it is found in appropriate instances that both forms of hypersensitivity can coexist 2 separable processes must occur in the immunologic apparatus For example, Gell and Hinde (1954) have suggested that delayed type hypersensitivity results from an antigenic stimulus that stops short of inducing plasma cell formation being confined to mononuclear cells Interestingly delayed type hypersensitivity occurs in many patients with agammaglobulinemia who have a pronounced deficiency in plasma cells and in the capacity to synthesize antibody Such patients show dermal reactivity following infections such as tuberculosis and Candida, or as a consequence of experimental sensitization by BCG vaccination or dinitrofluorobenzene or protein antigens coated with antibody (cf Porter, 1957 Good Bridges and Condie 1960) In all these cases cellular transfer with peripheral leukocytes was possible Yet some persons with agammaglobulinemia do not respond to allergization indeed one patient studied was found to be deficient in mononuclear cells during experimental inflammation An extensive review is presented by Good Kelly Rotstein and Varco (1962)

Emphasizing the role played by white cells in delayed allergies have been experiments showing that the allergic response is reduced significantly by depleting mononuclear cells through short term treatment with antilymph node serum or antimacrophage serum (Inderbitzen 1956 Wilhelm *et al* 1958, Waksman Arbouys and Arnason 1961 Pincus and Flick 1963), or through thoracic duct drainage prior to sensitization (Gowans *et al* 1962 Gowans 1962) or through thymectomy of rats at birth (Arnason Janković Waksman and Wennersten 1962) Affected are the allergic responses to tuberculin chemical contactants proteins inactivated vaccinia virus graft versus host reactions and in a measure allergic encephalomyelitis and homograft rejection

The number of lymphocytes stimulated by the process of sensitization is only a fractional part of the population as is evidenced by the finding of "competence" initially almost exclusively in nodes draining the site on which a sensitizing application is made Only 5 per cent of the lymphocytes attached to target tissue in the experiments of Rosenau

pig peritoneal cells Efforts are being made to relate this antibody (which appears to ab sorb to cell surfaces) to delayed type hyper sensitivity but no evidence has yet been presented of accomplishing passive transfer

THE SHWARTZMAN PHENOMENON

There remains to be mentioned a special sort of hemorrhagic necrotic reaction the Sanarelli Shwartzman phenomenon that can be produced in the skin and some other organs (chiefly the kidney) Accordingly the phenomenon is divided into the *local* and the *generalized* Shwartzman reactions It is not an antigen antibody mechanism but it pos sesses features in common with the Arthus reaction and its participation in acute dis ease processes is suspected

In this type of local tissue reactivity de veloped so ably by Shwartzman (cf review of 1937) sites in the skin of normal rabbits were prepared by injecting endotoxin-con taining culture filtrates of certain bacteria These sites would exhibit gross hemorrhage and necrosis within a few hours when cul ture filtrate was injected into the bloodstream between 8 and 32 hours later It was found that the skin preparatory factors and the reacting factors need not be identical or even immunologically related For example the local preparatory injection could be made with culture filtrates of *E coli* or *S typhosa* and the intravenous eliciting injec tion with meningococcal culture filtrates The active material in culture filtrates is identified with endotoxins of the bacteria the nitrogen free nontoxic lipopolysaccharide from *S marcescens* will both prepare and elicit the reaction The rabbit is the animal of choice for this experiment goats and horses show the effect guinea pigs respond irregularly and less intensely and mice and rats generally are found to be insusceptible However in certain specially bred strains of mice Shwartzman reactions have appeared upon an initial injection of bacterial polysac charide (Kelly *et al* 1957) In another highly inbred strain classic Shwartzman re actions were found to occur regularly (Arndt and Schneider 1960) As in the work of Kelly some of the mice reacted to the initial intradermal injection of endotoxin the authors relating this to preparation by gram negative microorganisms that were infecting the lung tissues without overt signs

It is possible to prepare the skin site with bacterial endotoxin or culture filtrates and to elicit the reaction by intravenous injection of certain nonbacterial materials—starch glyco gen agar or washed antigen antibody pre cipitates all of these being procedures which would affect guinea pig serum in vitro so that the serum would cause anaphylactoid shock Similarly endotoxin prepared skin will react locally when antigen antibody aggregates are allowed to form in vivo The reverse situa tion—namely substituting for the prepara tory injection a fully developed tuberculin reaction on a tuberculous animal and giving later an intravenous injection of a potent Shwartzman filtrate or even tuberculin—also results in a typical Shwartzman reaction (Freund 1934 guinea pig Stetson 1955 rabbits) tumor tissue in mice is said to offer a naturally prepared situs for Shwartzman effects since it responds with inflammation when potent bacterial filtrates are injected intravenously

From studies chiefly by Thomas and Stet son (1949) and Stetson (1951a b) it is known that after the preparatory injection polymorphonuclear leukocytes accumulate locally in the tissue around the smaller veins as cuffs and probably owing chiefly to the metabolic character of exudate poly morphonuclear leukocytes abnormal quan tities of lactic acid are produced there through aerobic glycolysis Changes (histologically inapparent) then occur in the adjacent vascular endothelium perhaps of a sort that render this tissue sensitive to the action of tissue protease Then upon the intravenous eliciting injection a peripheral vasoconstric tion occurs impairing the blood supply white cells and blood platelets clump and be come sequestered especially in the lung and attach markedly to the damaged endo thelium In the latter areas the aggregates form leukocyte platelet thrombi and actually occlude the small veins and the capillaries The death and the disintegration of involved vessels and of cells within the following 2 or 3 hours follow in the pattern of developing

by Janković and Dvorak (1962) in their finding that ribonuclease will inhibit temporarily interaction between competent rabbit lymph node cells and target cells

The relation of delayed type hypersensitivity to antibody-synthesis remains a major question even if the interpretation of 2 separate processes is correct Pappenheimer (cf Shaffer *et al* 1958) proposed that delayed type hypersensitivity may occur always as a first step in the production of antibody, representing a mechanism analogous to induced enzyme formation, that prepares the altered cells to produce circulating antibody electively upon a subsequent experience with the same antigen Yet delayed type hypersensitivity is not always found to precede antibody formation and the conclusion that this hypersensitivity becomes superseded when circulating antibody appears would require continuous and silent stimulation of newly maturing cells to sustain delayed type hypersensitivity

In seeking explanations for delayed type hypersensitivity in terms of antibody Burnet once suggested that eventually there is produced and put into the bloodstream a special antibody of such variety that it binds to the tissues with extreme readiness and is seldom to be encountered in the blood in an amount sufficient to permit passive transfer A search for such antibody was made by Cole and Favour (1955) and by Rauch and Favour (1960) in the plasma of tuberculin sensitive guinea pigs the equivalent of 80 ml being transferred At times a positive nontypical reaction to tuberculin was seen in the recipient but this approach appears to have been abandoned

Also in line with Burnet s suggestion is a hypothesis of delayed type hypersensitivity offered recently by Karush and Eisen (1962) and intended to unify all varieties of delayed hypersensitivity—tuberculin reactions contact dermatitis homograft rejection delayed type ocular reactions inhibition of cellular migration and other manifestations of tissue damage occurring in vitro (The hypothesis does not concern itself with the transfer factor of Lawrence and Pappenheimer) According to this concept the delay in the reaction appearing at a test site on a sensitive individual represents the time for synthesis of a very highly avid antibody its rate of production being sufficient to bind 10 per cent per hour of the antigenic complex in the test site during a 24 hour period, thereby producing gradually ascending inflammation The idea calls for stimulation and continued production of antibody possessing an exceedingly high avidity but at a concentration not to exceed 1×10^{-10} molarity in the serum (consequently not allowing transfer by serum) The test injection is pictured as immediately producing small amounts of soluble antigen antibody complexes These taken up from the circulation by the spleen and the nodal tissues would stimulate a recall synthesis leading to perhaps 4 fold as much newly synthesized antibody within 24 hours as had been present in a sensitized guinea pig before testing the rate of synthesis would necessitate a much more rapid turnover of the antibody than of total gamma globulin After reaction the production of this highly avid antibody would drop back to the previous undetectable concentration Adoptive transfer of contact type hypersensitivity would be ascribed to synthesis by the transferred cells of high affinity antibody Similarly cytotoxicity in tissue culture would result from antibody synthesis by the competent cells

As corollaries it would follow that (1) the highly avid antibody must appear in 5 or 6 days after injection of chemicals like dinitrochlorobenzene when the sensitizing injection was intradermal and not appear when the injection was intramuscular (2) the directive effect of mycobacterial adjuvant with haptene protein complexes would be explainable as causing production of highly avid antibody and (3) the rate of its synthesis must drop as soon as an animal has become sensitive although the synthesis of less avid antibodies is not hindered Whatever the merits of the hypothesis may be it will stimulate a more intensive study of antibody patterns

Another type of antibody cytophilic antibody has been described (cf Boyden 1963) being found in very low concentration in serum, the antibody is heat stable and absorbs to cell surfaces such as guinea

haps be described as the Frei Sulzberger Chase phenomenon The subject is of particular interest because certain noncutaneous routes of administering sensitizing compounds will alter the status even of adult animals deviating later attempts to induce delayed type hypersensitivity towards the same compound (reviewed by Chase 1959 1963 cf Coe and Salvin 1963 Battisto and Chase 1963) This type of unresponsiveness persists for 10 or more months and it is accompanied by *depression* of antibody synthesis The mechanism is unknown

ANTIHISTAMINES

Emphasis on the role of histamine in anaphylactic shock and in allergic reactions of immediate type excited the hope that the physiologic consequences of antigen antibody interaction might be avoided if the liberated histamine could be rendered ineffective Various approaches have been explored such as administration of the enzyme histaminase immunization by an artificial antigen containing histamine coupled to a protein and administration of special compounds possessing antihistaminic properties This last approach has provided a powerful adjunct in the treatment of allergic conditions The compounds influence in some degree other physiologically active substances (Loew 1950 Feinberg *et al* 1950) They are presumed to function as competitive inhibitors for the sites affected by histamine and they can be effective only as long as they can be maintained in tissues at an adequate level with respect to the histamine concentration

As with other proprietary compounds the products possess not only their trade names but also type names thus Pyribenzamine is one brand of tripelennamine hydrochloride Histadyl and Thenylene are different brands of methapyrilene hydrochloride Benadryl is a brand of diphenhydramine hydrochloride and so on (Cf Wilhelm 1961 for discussion of chemical classes)

The *evidence* for the protective action of these compounds against the effects produced in a normal animal by administration of histamine is impressive it extends to protection of the isolated guinea pig gut or uterine horn from contraction by histamine and to inhibition of vascular effects of histamine in the rabbit and other animals to the protection of guinea pigs from multiple lethal doses of histamine and from the bronchospasm caused by histamine aerosol At the same time it is found that most of these compounds do not modify the gastric secretogogue action of histamine When the antihistaminic compounds are tested for ability to protect anaphylactically sensitized guinea pigs against systemic shock by an intravenous injection of antigen larger amount are necessary (3 mg /Kg down to 1 mg /Kg) than are needed to deviate the effects of purely histamine shock

The variety in formulae has been welcomed because of individual reactions and requirements (cf Wilhelm 1961) All these compounds can produce undesirable side reactions such as drowsiness dizziness disorientation and gastrointestinal disturbances and occasionally (with overdose) even death hence the use of these substances by allergic individuals should be under medical supervision Often the antihistamines prove to be valuable in cases of allergic urticaria and allergic rhinitis although asthma especially is apt to be resistant Since the compounds function also as local anesthetic somewhat more so in this respect than procaine they may relieve the itching in poison ivy dermatitis but they do not modify in fundamental manner reactions that are of the delayed type

ACTH AND CORTISONES

Following the introduction of porcine ACTH (pituitary adrenocorticotropic hormone) in 1946 many diverse disease processes were found to be markedly ameliorated and among these were nearly all varieties of allergic manifestations Shortly afterward compound E of the adrenal cortex (cortisone) became available and was found to influence markedly the allergic state Other compounds including partially synthesized materials have since been developed (cf Jailer 1955) These materials include hydrocortisone 5 fluorohydrocortisone prednisone prednisolone methyl prednisolone dexamethasone and betamethasone They prove to be effective in relieving intrinsic and extrinsic asthma and as salves they control allergic eczema as well Treatment with

Arthus reactions The characteristic and prominent hemorrhage in the prepared site would follow as a consequence of necrosis of the vessel walls

As Rall *et al* (1957) point out, adrenergic vasoconstriction accompanying the eliciting injection could enhance local damage since epinephrine is known to exaggerate Shwartzman effects After making parallel studies on tuberculin sensitive rabbits injected with Old Tuberculin Stetson (1955) has suggested that the biologic activity of endotoxins may reflect a delayed type natural hypersensitivity of the rabbit to gram negative bacteria Evidence has been found also for this conclusion in rabbits hypersensitive to staphylococci (Atkins 1962b) Perhaps one could say that the Shwartzman event is to the Arthus and the delayed type allergies what the anaphylactoid is to the anaphylactic shock namely parallel and interwoven mechanisms for obtaining the same ultimate tissue response

Besides this *dermal* Shwartzman reaction the second aspect is the *generalized* Shwartzman reaction in which both injections must be given intravenously characteristically from 6 to 8 hours after the eliciting injection there is deposition of a fibrinoidlike homogeneous material particularly within the glomerular capillaries of the kidney which leads to occlusion of the circulation and results in bilateral renal cortical necrosis The determining event in initiating the generalized Shwartzman phenomenon appears to be intravascular coagulation The phenomenon can be duplicated when thrombin is injected directly into the renal arterial circulation (Robbins and Collins 1961) thus circumventing the normal action of the reticuloendothelial system (RES) in clearing fibrin (Lee 1962) Neither the local nor the generalized Shwartzman phenomena occurs if leukopenia has been induced previously as by nitrogen mustard

There has been active speculation that natural infections with bacteria may cause tissue preparation and that Shwartzman effects can occur owing to reacting factors provided by the infection itself by a proximal antigen antibody reaction or by a variety of other nonspecific stimuli this sequence has been surmised to be one possible factor operating in bacterial allergy and in the genesis of conditions such as pulmonary abscess or hemorrhagic lesions seen in meningococcemia (Black-Shaffer *et al*, 1947) Recently it has been found that when *pregnant* rats are placed on a diet of oxidized cod liver oil the pathology of the generalized Shwartzman phenomenon is duplicated without use of endotoxin (Stamler, 1959 McKay and Wong 1962)

MODIFICATIONS IN THE ALLERGIC STATE

Certain pharmacologically active materials serve temporarily to mitigate or to suppress allergic episodes of man Included are the so called antihistamines pituitary adrenocorticotrophic hormone (ACTH) cortisone (compound E), hydrocortisone, fluorohydrocortisone prednisone prednisolone and still others

Also for experimental purposes one can hold the immunologic apparatus in check for some days by means of antimetabolites such as 6 mercaptopurine methotrexate cyclophosphamide and the like administered just prior to and for some days after institution of a sensitizing procedure (cf Schwartz 1963 Hoyer Good and Condie 1963) Notable effects have been seen also by applying sublethal x irradiation for its effective depletion of lymphoid cells or by lowering the population of monocytic cells before intended sensitization by giving antilymphocyte or antimonocyte sera or by subjecting animals at birth to thymectomy thereby depressing the full development of lymphoid tissue

Under special conditions the immunologic apparatus can be rendered unresponsive to stimulation by particular antigens and yet retain responsiveness toward others (reviewed by Chase 1959 cf Bussard consulting editor 1963) Both synthesis of immunoglobulin and manifestations of delayed type hypersensitivity can be influenced

Of the many facets of immunologic tolerance induced tolerance to homografts already has been considered and mention need be made here only of induced unresponsiveness to sensitization with simple chemical compounds in guinea pigs which can per

ACTH has been shown to mitigate dyspnea and bronchoconstriction in man toward experimentally administered histamine and Mecholyl (Rose 1950) Likewise, these compounds are of benefit in the collagen vascular diseases thought to be allergic in nature

Cortisone and hydrocortisone were investigated at once and were found to possess as Germuth (1956) has remarked a marked antiflammatory effect owing perhaps to a vasoconstrictive action that leads to reduction in blood flow and inhibition of capillary permeability there is increased vascular tone lessened diapedesis and inhibition of lymphocytic reproduction These compounds do not affect the interaction of antigen and antibody for passive Arthus reactions can be evoked typically (Germuth and Ottinger 1950) although synthesis of antibody appears largely to cease upon hormonal treatment (cf Germuth *et al* 1951) reduction in circulating antibody does not run parallel with clinical improvement

Actively sensitized dogs and mice exhibit diminution in anaphylactic shock In rabbits both the Shwartzman reaction and serum disease are inhibited Intensive treatment with the hormones also diminishes delayed type reactions as to tuberculin A prototype has been seen in the markedly lessened inflammatory response of intensively treated animals injected with oil of turpentine (Osgood and Favour 1951 cf Gell and Hinde 1951)

Stringent medical supervision is required with these highly useful agents particularly with regard to occurrence of peptic ulcer diabetes and osteoporosis The physician must weigh carefully the temporary benefits that the patient may derive against the grave disadvantages that come from exhaustion of the adrenals and impairment of the normal hypothalamus pituitary adrenal axis Since inflammatory responses are suppressed there is the hazard with continued use that serious bacterial and fungal infections may become established With ACTH there is occasional allergization which usually is specific for the species of origin A hormone fastness also has been encountered infrequently

Although initial symptomatology usually returns with cessation of treatment in instances in which the offending allergen can be expected to disappear within a definitely limited time from the environment (pollens) or from tissue sites (e g following a reaction to injected penicillin), there may be no further symptoms after treatment is terminated

Endotoxins

The injection of cell walls of gram negative bacteria into experimental animals is followed by an array of toxic effects These include fever leukopenia skin reactions the Shwartzman phenomenon shock and death depending on the dose of material and the the route of its administration The active material or endotoxin can be extracted readily from intact bacteria or from purified cell wall preparations Endotoxin preparations derived from one bacterial species may differ quantitatively in potency from preparations from other bacteria but the effects produced by all endotoxins are qualitatively the same The lethal dose of endotoxin for most laboratory animals is of the order of 1 mg /Kg of body weight while the intravenous injection of less than a microgram causes a brisk fever in man rabbit and other species Because of the possibility that bacterial endotoxins are involved in various human disease states and because of the variety of the effects which they produce (Thomas 1954) much investigation has been carried out on the chemical nature of endotoxins and on the mechanisms by which they act

Extraction of gram negative bacterial cell walls with trichloracetic acid or aqueous phenol yields a toxic macromolecular complex of protein lipid and polysaccharide with a molecular weight of the order of 1 to 10 million Protein can be eliminated from such preparations without apparent loss of toxicity and much of the lipid can be removed from the resultant lipopolysaccharide without significant loss in endotoxin activity (Ribi *et al*, 1964), but no truly lipid free preparations have shown endotoxin activity

The polysaccharide of the endotoxin is the somatic or O antigen of the bacteria Purified preparations of these polysaccharides retain their antigenicity, and analysis of the products of hydrolysis of these has provided a basis for the chemical interpretation of their immunologic specificities In general the polysaccharides of all endotoxins contain D glucosamine heptose and glucose most also contain one or more additional sugars such as pentoses desoxyhexoses dideoxyhexoses mannose or galactosamine The patterns in which these sugars occur have permitted the arrangement of *Salmonella* into a system of chemotypes (Kauffmann *et al* 1960) which corresponds nicely to the older serotypic classification

It has been suggested that the toxicity of the lipopolysaccharide endotoxin resides primarily in the lipid and that the polysaccharide moiety merely serves a carrier function (Westphal and Lüderitz 1954) but little evidence has been forthcoming to support this view Indeed there is some doubt that endotoxins possess any intrinsic pharmacologic activity or toxicity as do exotoxins It has been pointed out that in many ways the effects produced by the injection of bacterial endotoxins into normal animals resemble the effects produced by the

injection of other antigens into specifically hypersensitive animals (Stetson 1955) For example the biphasic febrile response of normal rabbits to endotoxin is quantitatively and qualitatively much like that of tuberculin sensitive rabbits to injections of tuberculoprotein The skin reaction of normal rabbits to the intradermal injection of endotoxin closely resembles in its timing and histopathologic features the classic combined allergic reaction of Gell and Hinde (1954) The transient leukopenia thrombocytopenia and vasomotor phenomena seen during systematic reactions to endotoxin have their counterpart in typical anaphylaxis and Weil and Spink (1957) have pointed out many similarities between anaphylactic shock and shock caused by endotoxin

The Shwartzman phenomena (Shwartzman 1937) once were considered to be manifestations of a unique toxic property of endotoxins In the local Shwartzman phenomenon an intradermal injection of endotoxin is followed in several hours by an intravenous injection resulting in severe hemorrhagic necrosis at the site of the intradermal injection The generalized Shwartzman phenomenon is produced by 2 intravenous injections of endotoxin separated by a suitable time interval and results in the production of massive bilateral renal cortical necrosis It has been possible to reproduce both of these phenomena with other antigens in suitably sensitized or immunized animals (Lee 1963)

Therefore it may be that endotoxins possess biologic activity only by virtue of their antigenicity Obviously relevant to this problem is the demonstration by Schaedler and Dubos (1961 1964) that the reactivity of mice to endotoxins is very much dependent on or conditioned by the bacterial flora of their intestinal tracts Mice reared in an environment free of the usual enteric pathogens lack normal susceptibility to endotoxin On exposure of such mice to gram negative bacteria, they quite promptly become susceptible to the lethal effect of endotoxin These observations may indicate that susceptibility to endotoxin is due to sensitization by somatic antigens of intestinal bacteria The natural antibodies to somatic antigens of various enterobacteria probably arise as a consequence of active antigenic stimulation of the host by intestinal bacterial antigens as newborn animals or animals reared under germ free conditions have markedly reduced levels of such natural antibodies A number of considerations suggest that these antibodies may be the mediators of the various biologic activities of endotoxin (Landy and Weidanz 1964, Lee and Stetson 1960)

The repeated injection of sublethal amounts of an endotoxin results in a remarkable state of tolerance in which further injections of the same or any other endotoxin fail to produce their usual effects While this phenomenon has some operational and other similarities to the phenomenon of allergic desensitization the parallelism is not exact Endotoxin tolerance appears to depend in large part on the development of a marked increase in the phagocytic capacity of the fixed cells of the reticuloendothelial system with a correspondingly rapid clearance of endotoxin from the circulation Blockade of the reticuloendothelial system by Thorotrast or other colloidal material promptly restores the susceptibility to endotoxin (Beeson 1947) However tolerance also seems to depend to an appreciable extent on the prompt and vigorous humoral antibody response occasioned by the repeated exposures to the highly antigenic endotoxin Serum of tolerant animals is capable of conferring partial tolerance on normal recipients (Freedman 1960) Thus the more rapid removal of endotoxin from the circulation of a tolerant animal is probably due to prompt interaction with antibody with subsequent phagocytosis of the antigen antibody complexes The relative importance of the humoral and the cellular factors is still a matter of controversy but there is now no doubt that a tolerant state develops in man during typhoid fever (Greisman *et al* 1961) and the mechanism of endotoxin tolerance has become of more than academic interest

This brief account has made no mention of the capacity of bacterial endotoxin to elicit tumor hemorrhage to enhance the antibody response to unrelated antigens to initiate intravascular coagulation and to induce severe functional impairment of the

General Host Responses to Infection

Our purpose in this chapter is to describe and characterize certain physiologic reactions produced by infection in the mammalian host, particularly in man These host responses are fever and other alterations in control of body temperature circulatory changes hematologic abnormalities subjective feelings such as weakness and malaise and a miscellany of hormonal and other metabolic reactions The immune response and the actions of bacterial exotoxins are reasonably classified as systemic reactions to infection but are more specific than these others and are dealt with in detail elsewhere in this book

In a sense these systemic responses to infection can be regarded as the actual substance of disease They underlie the sensations which the individual human patient recognizes collectively as illness and they are the basis for the manifestations recognized by the clinician as the signs and symptoms of disease

The various local events initiated by implantation survival and replication of pathogenic microorganisms in the tissues of a susceptible host have been detailed in preceding chapters Inflammation and attendant phenomena such as phagocytosis are in*evitable biochemical and biophysical result*ants of the interaction of parasite and host However it is most difficult to avoid a teleologic or perhaps pragmatic concept of them as mechanisms of host resistance as defenses The local defense is often so efficient that no injury is recognized or that the only stigma is a subsequent immunologic response In other words the infectious process remains *subclinical* At other times local inflammation becomes grossly evident and signals disease by erythema pain swelling and impairment of function Finally in a minority of instances when local defenses are insufficient to contain the parasite or its products the general responses of the host come into play clinical illness is recognized and *infection* has evolved into *systemic disease*

The local inflammatory response s nonspecific in the sense that its general pattern is the same for injury produced by microbes antigens to which the host is allergic chemical toxins or physical trauma Similarly any or all of the systemic reactions of the infected host can be elicited by noninfectious disorders ranging from thrombosis to neoplasia The ease with which local exudation and phagocytosis are interpreted as host defenses contrasts with the difficulty experienced in demonstrating that many of the general responses described below have a role in protecting the host

FEVER

In man and in many animals the febrile response is a regular accompaniment of systemic disorders of many etiologies involving pathologic processes of almost every type So frequent is fever and so easily is it detected

reticuloendothelial system A comprehensive source of more detailed information concerning bacterial endotoxins has been provided recently by Braun and Landy (1964)

importance of humoral mechanisms in the resistance

The importance of avoiding endotoxin contamination in the experimental study of fever and the additional usefulness of endotoxin fever as a standard of comparison in the laboratory will be evident in the discussion to follow

Finally the fact that endotoxin is injurious to tissue must be borne in mind The delay between injection of endotoxin and the onset of fever led Beeson to suggest some years ago that the pyrogenic action of endotoxin might be secondary to tissue injury and that the lag period might be the time required for release of endogenous fever producing material from injured cells

Endogenous Pyrogens The extensive work of Menkin on inflammation included the isolation from sterile exudates of a substance *pyrexin* capable of producing high fever in animals Menkin postulated that pyrexin was the product of tissue injury responsible for the fever that accompanies many inflammatory states Comparison by Bennett and Beeson of the properties of pyrexin and of ordinary bacterial endotoxins indicated that their activities were identical in every respect and made it probable that that pyrexin owed its potency to endotoxin contamination The properties of pyrexin are unlike those of any of the endogenous pyrogenic substances that have been isolated in recent years

Proceeding on the assumption that normal tissues might contain a pyrogenic material which is released at the time of injury Bennett and Beeson attempted to extract fever producing substances from the tissues of the normal rabbit Of all cells and tissues tested only the polymorphonuclear leukocyte was found to contain a pyrogenic substance Extracts of polymorphonuclear leukocytes produced a brief monophasic fever after a very short lag period and animals continued to respond to daily injections of this material with the same amount of fever Furthermore leukocyte pyrogen was fully active in animals made tolerant to bacterial endotoxin and was destroyed by mild heating

Atkins and Wood searched for endogenous pyrogenic substances in animals given endotoxin Immediately after injection circulating blood was found to contain a pyrogen which resembled in every respect the endotoxin originally injected The blood then became nonpyrogenic but somewhat later another pyrogenic material appeared in the blood usually reaching a peak 2 hours after injection This second pyrogen usually referred to now as endogenous serum pyrogen was found to possess properties entirely different from those of the endotoxin originally injected Indeed by every biologic test it was identical in activity with leukocytic pyrogen Since one of the initial responses of an animal to injection of bacterial endotoxin is the development of a profound neutropenia it was suggested that endotoxin produced its febrile response by initial injury to leukocytes and possibly to other tissues with release of an endogenous tissue pyrogen which had a direct action on the cerebral temperature regulating centers By perfusing the carotid artery King and Wood were able to confirm a direct action of endogenous pyrogen on the brain

Additional studies indicate that the febrile responses to pneumococcal infection to hemolytic streptococcal infection to injection of myxoviruses to injection of antigen into hypersensitive animals and to injection of certain strains of staphylococci are mediated by an endogenous pyrogenic material which appears in the serum of the febrile animal and remains there throughout the febrile period While an initial neutropenia is not as striking in all of these experimental fevers as it is with endotoxin there is ample reason to believe that an important source of the serum pyrogen is the polymorphonuclear leukocyte

Recently Atkins and Snell have demonstrated thermogenic substances in normal rabbit tissues including skeletal muscle liver and kidney The pyrogens are demonstrable only after extraction of relatively large amounts of tissue and the febrile response does not completely imitate that obtained with leukocyte extract However the fact that pyrogen may be derived from cells other than the polymorphonuclear leukocyte is now established and many of the fevers in disorders that appear to involve no direct injury to leukocytes eventually may be explainable on this basis

that it is one of the first signs looked for when illness is suspected Practically speaking fever can be regarded as one of the dividing lines between health and disease

Pyrogenic Agents

Some bacteria fungi and viruses produce high fever in animals or man However other microorganisms are lacking in any immediate pyrogenic activity, furthermore fever is a common accompaniment of diseases that apparently do not involve invasion of the body by a biologic agent The obvious common denominator in disease is injury to tissues and cells Consequently it has long been believed that fever is the result of release of endogenous pyrogenic substances from injured tissues Evidence accumulated in recent years supports the existence of this mechanism particularly in fevers accompanying infectious diseases but detailed knowledge of the nature of the derangement of temperature regulation in many disorders is incomplete

Bacterial Pyrogens Until the 3rd decade of this century there had been many reports *that seemed to support unequivocally the* hypothesis that the products of injured tissue were responsible for the fever of disease However the discovery by Florence Seibert of bacterial pyrogens cast doubt on the significance of all earlier demonstrations of thermogenic activity in biologic materials and furthermore made it feasible to design valid experiments on the pathogenesis of fever It had been known for a long time that the intravenous infusion of a wide variety of fluids such as saline or glucose was likely to be followed by a shaking chill and several hours of fever Bacterial etiology of these fevers had been ruled out since sterile fluids retained pyrogenicity the tendency was to attribute injection fevers to an intrinsic property of the solution in use Seibert and her colleagues demonstrated that pyrogenic fluids contained small amounts of bacterial products and that the pyrogenic activity of these materials was unaffected by ordinary means of sterilization, including autoclaving These materials formerly referred to as bacterial pyrogens are now known to be the endotoxins of gram negative organisms Modern methods for the preparation of fluids for intravenous use are dependent on the avoidance of contamination because of the extreme difficulties encountered in removing these substances once they have made their appearance Bacterial endotoxins have been purified and are known to be lipopolysaccharides *Not only are they capable of inducing high* fever when injected into man or animals but also they possess other biologic activities including the induction of severe leukopenia hemorrhagic necrosis (Shwartzman phenomenon) shock and even death (Chap 12)

The ubiquity, the heat stability and the potency of these thermogenic bacterial products made it evident that the search for endogenous pyrogens released from injured tissue must employ technics that would avoid endotoxins It became mandatory for investigators to demonstrate that any so-called product of tissue injury with pyrogenic properties was not simply contaminated with exogenous bacterial substances

Endotoxin Fever The febrile response of most laboratory animals to endotoxin is rather characteristic There is a delay between injection of the material directly into *the circulation* and *onset of fever* *In man,* this lag period may be as long as 90 minutes but in most animals it is somewhat shorter With daily injections of the same dose of endotoxin there develops a state of resistance to its pyrogenic effect and this *tolerance* persists as long as regular injections are continued When injections cease the ability to respond with high fever is restored quickly The injection of particulate materials such as certain dyes suspensions of carbon or colloidal thorium dioxide (Thorotrast) increases the susceptibility of the normal or tolerant animal to the effects of endotoxin Endotoxin tolerance is not dependent on the classic antibody response and is nonspecific in the sense that an animal made resistant to an endotoxin from one bacterial species will also exhibit tolerance to endotoxins from nonrelated organisms Tolerant animals clear injected endotoxin from the bloodstream more rapidly than do normal animals the clearance involves the reticuloendothelial cells of the liver and the spleen However tolerance can be passively transferred by serum (the transfer is only partial but is definite) indicating the possible

mals with chronic pyelonephritis and in human subjects with chronic urinary tract infection produced by gram negative bacilli

The injection of endotoxin into the circulation or its release from organisms multiplying in tissue is almost certainly followed by injury to polymorphonuclear leukocytes and possibly to other cells with the release of pyrogenic material The endogenous pyrogen or pyrogens then apparently act directly on the cerebral centers governing body temperature and fever follows If the number of circulating granulocytes is reduced by administration of nitrogen mustard the amount of serum pyrogen demonstrable after infection of endotoxin is reduced materially (see Gillman Bornstein and Wood for summary of all studies) However such results are difficult to interpret in view of the debilitating effect of nitrogen mustard and the reduction in febrile response is perhaps not specific

Injection of endotoxin into the lateral ventricle of dogs into the *cisterna magna* of dogs or into the subarachnoid space of rabbits elicits high fevers which come on after little or no lag period which are unaccompanied by peripheral leukopenia and to which animals develop no tolerance despite repeated injections (Bennett Petersdorf and Keene) While further work is needed on this subject it seems likely that the action of endotoxin in producing fever may involve more than one mechanism and that endotoxin may be able to act directly on the cerebral centers

The Significance of Fever in Infectious Disease

Fever is no more than a physical sign of disease and therefore can be interpreted only in light of all information available to a physician However close attention to the type of fever and to certain accompaniments of fever can yield valuable diagnostic information The fever in many infectious diseases is so irregular that it offers little help in diagnosis but in some instances it can serve as a reliable guide to the physician in planning diagnostic procedures in evaluating therapeutic response and in indicating relapse or recurrence

Important points to be noticed in evaluating fever as a physical sign are height diurnal pattern type of temperature curve association with bradycardia association with chills and the occurrence of certain complications

Height of Fever Very high fevers may be seen in patients with meningitis poliomyelitis viral encephalitis and of course in other disorders of the central nervous system The hyperthermia observed under these conditions probably is a result of some direct involvement of the hypothalamus by the disease process

When the oral temperature in an adult with an infectious disease exceeds 105 F one should suspect the possibility of tuberculosis malaria relapsing fever or a gram negative bacillary infection such as tularemia brucellosis typhoid fever or pyelonephritis

There are some infections in which fever is not as prominent as might be expected For example the febrile response in diphtheria is usually less than 102 F and in the presence of pharyngitis with high fever streptococcal or viral infection is more likely Certain types of cutaneous ulceration such as anthrax and sporotrichosis are characterized by low grade fever and this may help the physician to differentiate these from tularemia or glanders Among mycotic diseases cryptococcosis is characteristically an afebrile disease

Type of Temperature Curve Elevation of body temperature by disease usually does not interfere with the normal diurnal variation and fevers are likely to be highest in the evening hours and lowest in the morning There are several other types of fever curve that maintain enough regularity in pattern to allow classification

When body temperature remains more or less continuously elevated throughout the 24 hours of the day the patient is said to have a *continuous* or a *sustained* fever This type of fever is characteristic of typhoid pneumococcal pneumonia rickettsial infections and certain viral diseases such as psittacosis

An *intermittent* or *quotidian* fever shows daily elevations with return of the temperature curve to the normal base line at least once during each 24 hour period If the patient s fever shows variations of more than 1 F during the 24 hour period of the day but does not return to the base line it is

The studies of Collins and Wood, Berlin and Wood and Kaiser and Wood have led to further understanding of the mechanism of production or release of leukocytic pyrogen The pyrogen is actively produced by leukocytes, and under appropriate environmental conditions in vitro leukocytes will continue to discharge increasing amounts of pyrogen into the suspending medium for several hours The production of this pyrogenic material involves active metabolic processes *within the cell* and *its release from the cell* is dependent on appropriate concentrations of electrolytes particularly potassium The pyrogen itself has not yet been completely purified but according to Rafter it appears to be a protein The inflammatory response apparently activates polymorphonuclear leukocytes to produce and release pyrogen Incubation of endotoxin and polymorphonuclear leukocytes in vitro results in production of leukocytic pyrogen

There is a degree of species specificity for both leukocytic and serum endogenous pyrogens This is not absolute but for example human leukocytes will not produce fever in rabbits The failure of investigators in the past to observe pyrogenic activity when inflammatory exudates of human origin were tested in laboratory animals is perhaps explainable on this basis

Endogenous Pyrogens in Man The best confirmation of a role of endogenous pyrogenic substances in the pathogenesis of fever in man comes from Snell s studies of sterile exudates from patients with fever With few exceptions the reinjection at a later time of these materials into the patient produced a sharp febrile response The pyrogenic activity was heat labile and it disappeared from body fluids with the subsidence of the pathologic process responsible for the fever Thus far attempts to demonstrate a pyrogen in human blood have been unsuccessful but it is possible that this failure may be related to dosage Indeed in animal experiments the detection of endogenous pyrogen in serum is sometimes difficult and requires the use of large volumes in testing

Steroid Fever Kappas and his associates have shown that a certain number of steroid hormones are pyrogenic when injected intramuscularly in man and there is some evidence for a role of these substances in rare instances of unexplained long-continued fever However, these materials produce no fever in laboratory animals and it is doubtful that they play a role in fever accompanying infectious disease Shulman has suggested that their pyrogenic action (which is evident only after *intramuscular* administration and *not after intravenous infusion in man*) may be secondary to extensive inflammation at the injection site

The Role of Endotoxin in Fever

An obvious possibility recognized for a long time is a role of endotoxin in the pathogenesis of the fever produced by gram negative organisms Inconclusive results were obtained in early studies conducted on the assumption that convalescence from a gram negative bacillary infection should be accompanied by a demonstrable tolerance to the pyrogenic action of endotoxin if the endotoxin were responsible for the fever of the disease The recent studies by Greisman and Hornick on the pathogenesis of typhoid fever in volunteers have clarified the situation considerably Typhoid confers tolerance to the pyrogenic effect of the endotoxin of the typhoid bacillus and to endotoxins from other species This tolerance is *demonstrable during convalescence* but not during the active phase of disease Indeed during active infection there is a hyperactivity to injected endotoxin (of homologous or heterologous origin) Presumably the patient with typhoid is exposed to a constant infusion of endotoxin and the effects of this type of exposure may be very different from those seen with *intermittent* injections Even in volunteers made tolerant by daily injections of endotoxin before the induction of typhoid fever *tolerance disappears* during the active infection but reappears immediately when disease is terminated by chemotherapy *Further studies* of these patients by Greisman and Wagner have shown that tolerance to the pyrogenic effect of endotoxin is *accompanied by an increased* ability to clear the bloodstream of endotoxin and that this increased clearance is specific *for endotoxins and does not apply* to other materials such as colloidal gold etc

Unequivocal tolerance to endotoxin has also been demonstrated by McCabe in ani

diseases may be explained by some ancillary protective effect of these illnesses against infection by the herpes virus Certainly the factors underlying the differential incidence of herpes labialis in various febrile diseases could be explored profitably

Fever alone is capable of producing enough disturbance in cerebral function to result in *delirium* Individual susceptibility to this complication of fever is quite variable preexisting disease of the brain (cerebral arteriosclerosis alcoholism) increases the likelihood of febrile delirium Disorientation is particularly common in typhoid psittacosis and rickettsial disease

A rather common complication of febrile illness in children is a *convulsion* While children with a family history of idiopathic epilepsy are somewhat more susceptible to febrile convulsions these do not necessarily herald the onset of epilepsy or some serious disorder of the nervous system

Ordinarily elevation of body temperature is accompanied by a proportional increase in pulse rate *Relative bradycardia* is seen in typhoid fever tularemia and psittacosis but it is by no means limited to these infections Individuals with acute meningitis may show impressive slowing of the pulse presumably as a result of increase in intracranial pressure A disproportionate bradycardia is also observed with considerable frequency in infectious mononucleosis mumps dengue primary atypical pneumonia and yellow fever (Faget s sign)

Patients with febrile disease often complain of *headache* but this is not invariable and fever itself is probably not responsible for the cephalgia Studies of the headache accompanying fever induced by the intravenous injection of typhoid vaccine have indicated that the pain is a result of dilatation and stretching of the large arterial vessels at the base of the brain similar to that seen in histamine headache It has also been shown that if one increases the cerebrospinal fluid pressure the intensity of headache is reduced

Whether fever alone is actually responsible for physical discomfort is an extremely *difficult question It is well known that* some patients with tuberculosis feel surprisingly well in the presence of high fever Indeed this characteristic of the febrile response in tuberculosis has been referred to as spes phthisica The fact that antipyretic drugs are also analgesics makes it very difficult to separate the symptoms of elevation of body temperature from the discomfort accompanying invasion of the body by the responsible infectious agent

Fever as a Protective Mechanism

Fever has sometimes been regarded as one of the body s protective responses to invasion by microorganisms The wisdom of using antipyretic drugs to reduce fever has been questioned from time to time on this basis Furthermore induction of fever by artificial means has been shown to have great therapeutic benefit in some diseases including syphilis of the central nervous system ophthalmic inflammations and certain types of arthritis

An extensive review by Bennett and Nicastri of the available evidence both experimental and clinical failed completely to give any support to the concept that elevation of body temperature per se exerts a protective effect or plays any important part in host defense On the other hand the harmful effects of hyperthermia are well substantiated and it is obvious that the increased demands on the heart accompanying elevation of body temperature may exert a deleterious effect in individuals with heart disease Therefore there is little question about the advisability of reducing body temperature in many patients with fever

CIRCULATORY CHANGES

Many hemodynamic changes observed in animals or patients with infectious disease are directly related to changes in body temperature Others result from direct damage to the heart the pericardium the vessels or the central nervous system by the infecting agent or its products When myocardial damage is already present high fever or the stress of infection may lead to cardiac decompensation For example individuals with mitral stenosis sometimes develop heart failure in the course of relatively trivial viral respiratory illness Whether these infections exert their seemingly dispropor

referred to as a *remittent* fever Very wide swings of temperature of a remittent or intermittent pattern constitute a *hectic* or *septic* fever Remittent fevers are characteristic of patients with brucellosis, and the fever of typhoid is sometimes mildly remittent rather than sustained

Of course hectic fevers are characteristic of pyogenic infections (particularly when there is localized suppuration) tuberculosis and malaria A hectic temperature curve which shows 2 distinct spikes during the 24 hours of the day is referred to as a *double quotidian* curve and is a classic sign of gonococcal endocarditis or kala azar At the present time in the United States a double quotidian curve is more suggestive of miliary tuberculosis than anything else although many of these patients will show the pattern for only a few days a a time

Occasionally one sees a hectic temperature curve in which the normal diurnal gradient seems to have been reversed The patient will show high spiking fever in the morning hours This pattern so-called typhus inversus is highly suggestive of tuberculosis

Recurrent or *relapsing* fevers consist of short febrile episodes of a few days interspersed with similar periods of normal temperature Rat bite fever cause by *Spirillum minus* relapsing fever (*Borrelia*) malaria and chronic menigococcemia commonly elicit this type of febrile response Recurrent fevers are not infrequent in patients with tuberculosis and are also seen in the type of brucellosis which occurs in the Mediterranean area (hence the name undulant fever) although brucellosis in the United States is accompanied by an intermittent or mildly remittent fever in most instances

Many viral diseases are biphasic and are characterized by a few days of febrile illness apparent recovery and then a second period of illness and fever The minor illness and the major illness of poliomyelitis exemplify this type of pattern Infections by the Coxsackie virus dengue smallpox yellow fever Colorado tick fever lymphocytic choriomeningitis and infectious mononucleosis are other viral or presumed viral infections in which there may be two rather distinct periods of febrile illness separated by a few days of well being

Rigors For reasons that are incompletely understood shaking chills are characteristic of certain infections and extremely rare in others In evaluating the significance of chills it is important for the physician to remember that the administration of antipyretic drugs such as aspirin can induce chills in patients with fever of almost any type and it is necessary to differentiate chilliness, chilly sensations and true chills Repeated chills suggest pyogenic infection with intermittent discharge of bacteria into the bloodstream such as can occur in infections of the liver the biliary tract and the kidneys Malaria of course is characterized by chills at rather regular intervals A single chill in a patient with bacterial pneumonia suggests pneumococcal etiology, and the occurrence of repeated chills is strong evidence that the pneumonia is caused by some other organism

Chills are quite rare in certain diseases The onset of typhoid is usually unaccompanied by chill and rigors are unusual in uncomplicated viral hepatitis Therefore in a patient with jaundice the presence of true chills is strong evidence for leptospiral infection or ascending cholangitis Repeated chills would also be good evidence for a diagnosis of bacterial endocarditis or bacterial pneumonia rather than rheumatic fever or pulmonary infarct

Other Accompaniments of Fever Fever often activates the herpes simplex virus resulting in the production of so-called *fever blisters* Some infections are more likely to be complicated by herpes labialis than are others Fever blisters are very common in pneumococcal infections malaria, rickettsioses meningoccemia and streptococcal infections especially scarlet fever In contrast, the presence of herpes labialis is strong argument against a diagnosis of primary atypical pneumonia typhoid, tuberculosis smallpox brucellosis or staphylococcal disease

The fact that artificial fever therapy results in the appearance of fever blisters in almost half of patients undergoing this type of treatment seems to indicate that it is the elevation of body temperature itself that activates the virus Therefore the rarity of fever blisters in certain febrile infectious

diseases may be explained by some ancillary protective effect of these illnesses against infection by the herpes virus Certainly the factors underlying the differential incidence of herpes labialis in various febrile diseases could be explored profitably

Fever alone is capable of producing enough disturbance in cerebral function to result in *delirium* Individual susceptibility to this complication of fever is quite variable preexisting disease of the brain (cerebral arteriosclerosis alcoholism) increases the likelihood of febrile delirium Disorientation is particularly common in typhoid psittacosis and rickettsial disease

A rather common complication of febrile illness in children is a *convulsion* While children with a family history of idiopathic epilepsy are somewhat more susceptible to febrile convulsions these do not necessarily herald the onset of epilepsy or some serious disorder of the nervous system

Ordinarily elevation of body temperature is accompanied by a proportional increase in pulse rate *Relative bradycardia* is seen in typhoid fever tularemia and psittacosis but it is by no means limited to these infections Individuals with acute meningitis may show impressive slowing of the pulse presumably as a result of increase in intracranial pressure A disproportionate bradycardia is also observed with considerable frequency in infectious mononucleosis mumps dengue primary atypical pneumonia and yellow fever (Faget s sign)

Patients with febrile disease often complain of *headache* but this is not invariable and fever itself is probably not responsible for the cephalgia Studies of the headache accompanying fever induced by the intravenous injection of typhoid vaccine have indicated that the pain is a result of dilatation and stretching of the large arterial vessels at the base of the brain similar to that seen in histamine headache It has also been shown that if one increases the cerebrospinal fluid pressure the intensity of headache is reduced

Whether fever alone is actually responsible for physical discomfort is an extremely difficult question It is well known that some patients with tuberculosis feel surprisingly well in the presence of high fever Indeed this characteristic of the febrile response in tuberculosis has been referred to as spes phthisica The fact that antipyretic drugs are also analgesics makes it very difficult to separate the symptoms of elevation of body temperature from the discomfort accompanying invasion of the body by the responsible infectious agent

Fever as a Protective Mechanism

Fever has sometimes been regarded as one of the body s protective responses to invasion by microorganisms The wisdom of using antipyretic drugs to reduce fever has been questioned from time to time on this basis Furthermore induction of fever by artificial means has been shown to have great therapeutic benefit in some diseases including syphilis of the central nervous system ophthalmic inflammations and certain types of arthritis

An extensive review by Bennett and Nicastri of the available evidence both experimental and clinical failed completely to give any support to the concept that elevation of body temperature per se exerts a protective effect or plays any important part in host defense On the other hand the harmful effects of hyperthermia are well substantiated and it is obvious that the increased demands on the heart accompanying elevation of body temperature may exert a deleterious effect in individuals with heart disease Therefore there is little question about the advisability of reducing body temperature in many patients with fever

CIRCULATORY CHANGES

Many hemodynamic changes observed in animals or patients with infectious disease are directly related to changes in body temperature Others result from direct damage to the heart the pericardium the vessels or the central nervous system by the infecting agent or its products When myocardial damage is already present high fever or the stress of infection may lead to cardiac decompensation For example individuals with mitral stenosis sometimes develop heart failure in the course of relatively trivial viral respiratory illness Whether these infections exert their seemingly dispropor

tionate effect on the circulation by aggravating the retention of sodium or by direct action on the myocardium is not known However it is clear that support of myocardial function becomes a major therapeutic objective when such pre-existing lesions complicate the course of infectious disease

In this section no attempt will be made to categorize all possible circulatory changes associated with specific infectious diseases Rather the major types of alteration in body hemodynamics will be discussed and selected examples described

Central Circulatory Failure

Circulatory failure may be central or peripheral Central circulatory failure is the term used to describe any impairment of the heart as a pump which results in a cardiac output that is inadequate for the body s needs It may be the result of damage to heart valves as can occur in the course of subacute bacterial endocarditis It may be the result of myocarditis of viral or rickettsial origin The heart is also directly affected by diphtheria toxin and by severe bacterial infections such as meningococcemia Heart failure may be the result of pericardial disease with the development of acute tamponade as can occur in acute purulent pericarditis or the gradual development of heart failure as is seen in chronic tuberculous pericarditis

It seems to be unnecessary here to rehearse the pathogenesis of the clinical manifestations of congestive heart failure When evidence of impairment of myocardial function occurs in the course of infectious disease the therapeutic measures employed differ in no important way from those utilized in individuals without infectious disease The presence of known heart disease of any type should alert the clinician to the possibility of incipient congestive heart failure

Bacterial infections of the lung are often associated with transient bouts of cardiac arrhythmia such as atrial fibrillation These arrhythmias usually disappear as the infection is brought under control and do not necessarily indicate pre-existing heart disease or significant myocardial damage

Electrocardiographic abnormalities can be detected with considerable regularity in a number of common infectious diseases including viral diseases such as poliomyelitis mumps measles etc but there is little evidence that these transient abnormalities are of immediate or long term physiologic significance However, the potential seriousness of otherwise banal infections in terms of possible damage to the myocardium must always be borne in mind by the clinician

Peripheral Circulatory Failure

The picture of peripheral circulatory failure or shock with severe hypotension tachycardia cold clammy extremities evidence of cerebral ischemia thirst etc can be elicited by several mechanisms In most instances of infectious disease shock probably results from a combination of several physiologic alterations which lead to a reduction in the circulating blood volume or extensive local or general vasodilatation

In any severe systemic disease irreversible damage to body cells by interference with metabolism or by toxic injury can result in a drop in blood pressure and peripheral circulatory failure When this type of shock appears in an individual with an active infectious disease the only lasting therapy is that directed toward elimination of the infectious agent or toward neutralization of toxic products of the offending microorganisms While measures to support the circulation are indicated they will inevitably fail if employed without specific attention to the infectious agent responsible for the damage to body cells Because damage to cells may be irreversible specific therapy of an infection with antibiotics or by appropriate surgery may fail to modify peripheral circulatory failure and patients may go on to die despite the achievement of a bacteriologic cure This is seen occasionally in patients with bacterial meningitis and particularly in individuals with pneumonic plague

Reduction in blood volume in an infectious disease may result from dehydration a frequent event in very young or very elderly patients Severe diarrhea or vomiting causes increased fluid loss and in many ill individuals dehydration develops as a result of failure of the individual to maintain an intake of fluids through anorexia unwillingness to cooperate or neglect

In disease produced by meningococci various rickettsiae and certain viruses responsible for the so-called hemorrhagic fevers there is severe damage to capillaries and venules with transudation of electrolytes water and plasma proteins into the extravascular tissues These patients may develop peripheral circulatory failure as a result of the reduction in circulating blood volume despite the presence of edema

Defervescence, Hypotension and Hyperthermia. A rapid rise in body temperature such as may occur with a shaking chill involves massive autonomic activity of the adrenergic type In an individual with rising temperature there is extreme peripheral vasoconstriction with a grayish pallor there may be elevation of blood pressure agitation and pupillary dilatation Perhaps more important as a source of clinical confusion are the changes accompanying rapid defervescence In this situation there is extreme cholinergic activity with peripheral vasodilatation diaphoresis and other changes such as pupillary constriction and involuntary urination With any intense activity of the mechanisms for dissipation of heat there is very likely to be a drop in both systolic and diastolic blood pressure Patients undergoing rapid defervescence may be uncomfortable because of profuse sweating but the hypotension that so regularly accompanies this heat loss is not ordinarily dangerous and certainly does not signify failure of the peripheral circulation Hypotension is seen regularly after a paroxysm in malaria it is a frequent accompaniment of spontaneous crises is pneumococcal pneumonia and it occurs with regularity following single chills in individuals with transient bacteremia

If defervescence is induced by drugs such as aspirin there may be considerable drop in blood pressure a striking example of this being the picture that occurs when individuals with typhoid fever are given an antipyretic drug The administration of cortisone with rapid defervescence can be followed by hypotension which may last for several hours Similarly in individuals whose defervescence is the result of a dramatic response to the administration of antibiotics there may be moderate hypotension for as long as a day or two

With the exception of occasional individuals with pre existing hypertension the drop in blood pressure accompanying defervescence rarely has any serious result although it is certainly preferable to avoid too rapid cooling in febrile patients whenever possible However it is most important to avoid confusing this type of transient hypotension with true peripheral circulatory collapse

The Role of Endotoxin in Shock. Among the many potent biologic effects of the endotoxins elaborated by gram negative bacteria is their ability to produce hypotension and eventually severe circulatory failure Before discussing a possible role of endotoxin in the shock associated with various infectious disease it should be mentioned that there is some evidence to support the idea that these substances have a role in shock of non infectious origin The possibility that the irreversibility of hemorrhagic shock is a result of absorption of preformed endotoxin from the intestinal lumen has been explored extensively and has not yet been excluded However a discussion of the role of endotoxin in the pathogenesis of noninfectious shock is not germane at this point and the reader is referred to the publications of Fine in this connection

Gilbert has reviewed the mechanisms of the circulatory changes produced by endotoxin The available information is rather difficult to interpret in view of the fact that injection of endotoxin produces a different sequence of changes in various animal species Therefore as in other areas utmost caution must be exercised in applying the findings in various animals to man However despite the marked species differences several things can be said about the effect of endotoxin on the circulatory system

The effect of endotoxin is not limited to a single portion of the cardiovascular system Following injection of endotoxin in most species there is a stage of intense increase in total peripheral resistance which with large doses is followed by a later fall as vasodilatation occurs This sequence of changes fits direct observations on the effect of endotoxin on the reactivity of small vessels to epinephrine With low doses of endotoxin there is sustained vasoconstriction

with moderate doses there is vasoconstriction followed by dilatation and with lethal *doses vasodilatation may be the only re* action observed The fact that peripheral resistance is quite high in the initial stages of endotoxin shock fits the observation that the administration of vasodilators prior to endotoxin is protective and that vasocon strictors have no such effect

Profound hypotension is a part of the reaction to large doses of endotoxin in every species studied This appears to result from impairment of venous return to the heart and the decreased venous return is doubt less a result of pooling of blood in capillaries and veins Among the striking species dif ferences in the effect of endotoxin is the location of this pooling For example there is entrapment in the liver and other abdom inal viscera of the dog However, the changes *in the dog* are not seen in the monkey the cat or in man In these last three, it cannot yet be stated with certainty where the major portion of the pooling occurs However it is clear that the picture of endotoxin shock in man and other animals is not attributable to any reduction in total blood volume but *is a result of a redistribution of blood within* the intravascular space

The relative roles of catechol amines sero tonin histamine and other vasoactive agents known to be released into the circulation after the injection of endotoxin are unknown at the present time

Cortisone and related steroids are clearly capable of modifying the reaction of animals to endotoxin particularly when these hor mones are administered beforehand but *there is very little evidence that the cir*culatory failure produced by endotoxin is a result of adrenal insufficiency Indeed the circulating levels of these steroids are elevated in *individuals with reversible endo* toxin shock and it is possible also to demon strate increased peripheral utilization of injected steroids In contrast in fatal endo toxin shock there is evidence that the high levels of circulating hydrocortisone result partly from an impairment of peripheral *utilization*

A possible exception to the statement that endotoxin does not produce its effects through adrenal insufficiency is the occa sional occurrence of massive bilateral adrenal hemorrhage (Waterhouse Friderichsen syn drome) in individuals with certain types of bacteremia While adrenal apoplexy is not limited to patients with gram negative in fections it is far more frequent with this group and its relationship to endotoxin and to shock seems to be well established

HEMATOLOGIC CHANGES

Infectious diseases of many types are accompanied by changes in the formed elements of the blood These alterations include variation in the number and the type of circulating leukocytes, anemia ac *celeration of the sedimentation rate* of erythrocytes and alterations in the numbers of circulating platelets None of these hema tologic abnormalities is peculiar to infectious disease the situation being similar *to that* for the other systemic manifestations dis cussed in this chapter Despite an enormous body of clinical information concerning the alterations to be expected in specific in fections of one type or another our knowl edge of the mechanisms responsible for *many of the changes is scant*

Changes in Leukocytes

The characteristic finding in most in stances of infection by pyogenic bacteria is a polymorphonuclear leukocytosis The neu trophilic leukocytes are of great importance in the initial stages of the acute inflammatory response and it is highly probable that the increase in the number of these cells in the circulation is related in some way to the *inflammatory response* A number of substances have been described which are thought to influence the level of circulating polymorphonuclear leukocytes but at the *present time, their status remains* in doubt

In recent years, the dynamics of pro duction and distribution of polymorpho nuclear leukocytes have been studied by radioactive isotopic technics Athens has reviewed the current status of leukokinetics in an excellent monograph Polymorphonuclear leukocytes are produced continuously in the bone marrow and mature granulocytes are stored in a medullary pool before entry into the circulation Further there are two

pools of granulocytes in the circulating blood and these are of approximately equal size The first pool consists of cells which are actively circulating and the second consists of granulocytes which are sequestered or marginated in various capillary beds Acute changes in the number of circulating granulocytes following such stimuli as exercise or the injection of catechol amines are apparently a result of entry of these marginated leukocytes into the circulating pool

Other stimuli such as endotoxin and presumably active infection may cause an initial increase in the number of granulocytes in the marginated pool and hence transient neutropenia but this is followed by a striking increase in total leukocytes in the circulation This increase arises from reentry of cells from the marginated pool and the addition of new cells from the stores in the bone marrow

As yet the influence of infectious disease on the rate of production and maturation of granulocytes has not been carefully studied but probably there is stimulation of production and more rapid maturation It is highly probable that leukocytosis in infections is attributable initially to mobilization of granulocytes from the pools and that the participation of the bone marrow is reflected later in the eventual appearance of less mature forms of granulocytes

There are certain bacterial infections such as typhoid fever in which leukopenia is an almost constant finding at some stage of the disease In many other infections such as brucellosis tularemia and viral diseases (particularly in the early stages) including measles dengue Colorado tick fever smallpox and influenza a significant reduction in the total number of circulating leukocytes is seen with considerable frequency In almost any type of overwhelming infection there may be a reduction in the total peripheral leukocyte count. It cannot be stated with certainty what accounts for the leukopenia characteristic of these diseases

One particular type of leukopenia is of considerable significance The injection of bacterial endotoxin or of suspensions of bacteria is followed immediately by a sharp reduction in circulating granulocytes Within 30 minutes to 4 hours there is observed a rebound leukocytosis and this appears to be a result of release of cells from the marginated pool and the bone marrow reservoir

The initial leukopenia probably results from margination and sequestering of leukocytes in capillary beds particularly in the lung Clinically this transient reduction and elevation in peripheral granulocytes may be important in that misleadingly low counts will result if blood samples are taken immediately following a shaking chill and misleadingly high counts will be found if samples are taken during the rebound 4 or 5 hours after a chill

As is evident from the discussion above almost all studies on alterations in numbers of granulocytes during infections have dealt with cells in the blood Such studies may have limited significance since the polymorphonuclear leukocyte carries out its function for the most part after leaving the circulation Technics have not yet been devised for measuring the concentration and the life span of granulocytes in tissues

Eosinophilia, relative or absolute may be observed in the course of recovery from infections of several types It is common in parasitic infestations and is also likely to be seen in any individual with extensive skin rash The mechanisms which lead to blood or tissue eosinophilia are unknown although the association of these cells with hypersensitivity reactions is probably important Supravital studies indicate an almost selective avidity of the cells for the ingestion of antigen antibody complexes Almost nothing is known about the factors controlling production of eosinophils by the bone marrow their entry into the bloodstream etc

The lymphocytes of the circulating blood continue to pose a great mystery in terms of function It is generally agreed that they play some part in antibody formation and it is highly probable that certain lymphocytes at least, are capable or undergoing transformation into macrophages at sites of inflammation A large majority of lymphocytes appear to have a very long life span although one small population exhibits a much shorter period of viability Virtually nothing is known of the stimuli which lead to the appearance of lymphocytosis in the course of certain infectious diseases Absolute lym

with moderate doses there is vasoconstriction followed by dilatation and with lethal doses vasodilatation may be the only reaction observed The fact that peripheral resistance is quite high in the initial stages of endotoxin shock fits the observation that the administration of vasodilators prior to endotoxin is protective and that vasoconstrictors have no such effect

Profound hypotension is a part of the reaction to large doses of endotoxin in every species studied This appears to result from impairment of venous return to the heart and the decreased venous return is, doubtless a result of pooling of blood in capillaries and veins Among the striking species differences in the effect of endotoxin is the location of this pooling For example there is entrapment in the liver and other abdominal viscera of the dog However, the changes in the dog are not seen in the monkey the cat or in man In these last three it cannot yet be stated with certainty where the major portion of the pooling occurs However it is clear that the picture of endotoxin shock in man and other animals is not attributable to any reduction in total blood volume but is a result of a redistribution of blood within the intravascular space

The relative roles of catechol amines serotonin histamine and other vasoactive agents known to be released into the circulation after the injection of endotoxin are unknown at the present time

Cortisone and related steroids are clearly capable of modifying the reaction of animals to endotoxin, particularly when these hormones are administered beforehand but there is very little evidence that the circulatory failure produced by endotoxin is a result of adrenal insufficiency Indeed the circulating levels of these steroids are elevated in individuals with reversible endotoxin shock and it is possible also to demonstrate increased peripheral utilization of injected steroids In contrast in fatal endotoxin shock there is evidence that the high levels of circulating hydrocortisone result partly from an impairment of peripheral utilization

A possible exception to the statement that endotoxin does not produce its effects through adrenal insufficiency is the occasional occurrence of massive bilateral adrenal hemorrhage (Waterhouse Friderichsen syndrome) in individuals with certain types of bacteremia While adrenal apoplexy is not limited to patients with gram negative infections, it is far more frequent with this group and its relationship to endotoxin and to shock seems to be well established

HEMATOLOGIC CHANGES

Infectious diseases of many types are accompanied by changes in the formed elements of the blood These alterations include variation in the number and the type of circulating leukocytes, anemia acceleration of the sedimentation rate of erythrocytes, and alterations in the numbers of circulating platelets None of these hematologic abnormalities is peculiar to infectious disease the situation being similar to that for the other systemic manifestations discussed in this chapter Despite an enormous body of clinical information concerning the alterations to be expected in specific infections of one type or another our knowledge of the mechanisms responsible for many of the changes is scant

Changes in Leukocytes

The characteristic finding in most instances of infection by pyogenic bacteria is a polymorphonuclear leukocytosis The neutrophilic leukocytes are of great importance in the initial stages of the acute inflammatory response, and it is highly probable that the increase in the number of these cells in the circulation is related in some way to the inflammatory response A number of substances have been described which are thought to influence the level of circulating polymorphonuclear leukocytes but at the present time their status remains in doubt

In recent years the dynamics of production and distribution of polymorphonuclear leukocytes have been studied by radioactive isotopic technics Athens has reviewed the current status of leukokinetics in an excellent monograph Polymorphonuclear leukocytes are produced continuously in the bone marrow and mature granulocytes are stored in a medullary pool before entry into the circulation Further there are two

a result of involvement of the spleen in these diseases and occasionally the anemia has been relieved by splenectomy

As has been mentioned chronic infections of several types may be accompanied by anemia This is commonly referred to as secondary anemia, but a preferable term according to Wintrobe is simple chronic anemia There is very little alteration in the morphology of erythrocytes in this anemia and it bears a close resemblance to that observed in chronic debilitating disease of several types including disseminated tumors and chronic renal failure

Among infections in which anemia may become very prominent is subacute bacterial endocarditis In the vast majority of instances the anemia is only moderate and is not a serious clinical problem Brucellosis tuberculosis prolonged suppuration etc are also regularly accompanied by mild anemia The decrease in circulating erythrocytes in chronic infection apparently results from a combination of depression of the bone marrow and a shortened life span of the red cells One of the earliest changes noted in infection is a reduction in plasma iron content and in serum iron binding capacity This cannot be influenced by the administration of iron whether given in the usual form or as transfused erythrocytes There is delay in the incorporation of labeled iron into erythrocytes and this is mirrored by the clinical observation that individuals with chronic infection are unable to respond to such stimuli as bleeding or an acute hemolytic episode with an outpouring or reticulocytes Indeed the response of patients with pernicious anemia to therapy with vitamin B_1 may be interrupted by an intercurrent infection Other chemical changes observed in the course of the anemia of chronic infection include elevation of serum copper elevation of erythrocyte protoporphyrin and an increased excretion of coproporphyrin There is usually no evidence of increased hemolysis in the form of elevation of urobilinogen or of serum bilirubin but measurement of the life span of erythrocytes in chronic infection has regularly demonstrated a shortening At the present time the only definitive treatment for the anemia of chronic infection is control of the infectious process itself With convalescence there is prompt correction in the hematologic defect

Changes in Platelets

Thrombocytopenia has been observed in a large number of infectious diseases particularly those accompanied by bacteremia The mechanism of the reduction in circulating platelets is not known but may be sequestration in areas where there has been damage to endothelium Purpura is a relatively common manifestation of severe bacterial infections such as meningococcemia and bacterial endocarditis but the relative role of thrombocytopenia capillary fragility and other factors in these conditions remains to be worked out

A lowered number of platelets although not a reduction to levels that might be expected to lead to significant bleeding is observed with great regularity when counts are made in patients with many different types of infectious disease including typhoid the rickettsioses the viral exanthemata, subacute bacterial endocarditis and infectious hepatitis

Whether the ability of the bone marrow to produce platelets is actually impaired in the course of any of these infections is a question which has not been investigated It is probable that occasional instances of secondary thrombocytopenic purpura are attributable to hypersplenism in the course of chronic infections but this seems to be rare

WEAKNESS AND MALAISE

Patients with acute or chronic infectious disease complain of a variety of unpleasant somatic sensations These include weakness fatigability anorexia generalized aching etc While a patient may attempt to describe his symptoms in many ways one ordinarily has only to look at him to realize that he is miserable and uncomfortable beyond his ability to vocalize or to localize the seat of his complaints

Despite the great frequency of these ill defined manifestations of illness surprisingly little is known about the basic mechanisms involved The manifestations are in no way peculiar to infection and indeed many of

phocytosis of a mild degree is seen characteristically in the later stages of certain common viral diseases such as mumps and measles For mysterious reasons an enormous lymphocytosis is characteristic of pertussis In this disease the lymphocytosis appears in the early stages of infection and persists well into convalescence Finally a peculiar disease acute infectious lymphocytosis, presumably of viral origin, is seen primarily in children and is characterized by enormous increases in the peripheral count of mature lymphocytes

There are several other diseases in which lymphocytosis is seen with regularity and in which the increase in lymphocytes is attributable to atypical cells The best example of this is infectious mononucleosis a disease of presumed but not proved viral origin Similar cells are seen in other viral diseases particularly in infectious hepatitis Indeed these atypical lymphocytes are often referred to as virocytes This change in morphology remains unexplained Similar alterations have been described in response to stress but the significance of this for viral diseases is doubtful

Monocytosis has been noted with considerable regularity during the period of convalescence from many acute bacterial infections Monocytosis is sometimes especially prominent in patients with tuberculosis subacute bacterial endocarditis or listeria infections and occasionally it is seen in typhoid or brucellosis The mechanism of these fluctuations in circulating monocytes is entirely unknown and other than to point out their occurrence little else can be said

Changes in Erythrocytes

Perhaps the most frequent change involving circulating erythrocytes in the course of infectious diseases is an increase in their *sedimentation rate* While a number of factors are known to influence the rate at which erythrocytes will settle from plasma it cannot be said with certainty which of these are involved in the acceleration observed in infectious diseases The addition of fibrinogen bacterial polysaccharides and of various plasma globulin fractions will increase erythrocyte sedimentation Albumin appears to inhibit sedimentation and, interestingly enough gamma globulins are less effective than alpha and beta globulins in accelerating the sedimentation rate Further more it appears that the proportion of components of plasma protein is more important than the absolute concentration of any single one The rate of erythrocyte sedimentation is accelerated in the vast majority of infectious diseases particularly systemic infections Of course, high sedimentation rates also occur in noninfectious diseases The clinical usefulness of the test lies in its ability to indicate organic illness and to substantiate subsidence of infection or other inflammatory disease

Anemia is a common complication of infection It is seen more frequently in chronic prolonged infectious diseases than in acute bacterial and viral disorders

Acute hemolytic anemia may complicate the course of viral infections including acute viral hepatitis and herpes simplex Primary atypical pneumonia due to mycoplasma infection may be complicated by hemolytic anemia the mechanism presumably being related to the frequent development of cold agglutinins in this disease

Excepting Oroya fever the bacterial infection in which acute hemolytic anemia is seen with greatest regularity is *Clostridium welchii* bacteremia There is massive destruction of red cells hemoglobinuria and severe prostration Not infrequently control of the bacterial infection is to no avail the patient finally dying as a result of the renal complications of the massive hemolysis Despite the fact that several other bacteria are known to produce hemolysins there is little evidence except in the case of the Welch bacillus that these hemolysins are particularly active in the course of infection in man However hemolysis of significant degree has been observed in typhoid (it is probably a more regular occurrence than has been recognized previously) and rarely in beta hemolytic streptococcal infections and in infections by the influenza bacillus

Occasional instances of hemolytic anemia have been reported to complicate the course of tuberculosis and other infectious granulomata such as those produced by fungi In several instances this has appeared to be

a result of involvement of the spleen in these diseases and occasionally the anemia has been relieved by splenectomy

As has been mentioned chronic infections of several types may be accompanied by anemia This is commonly referred to as secondary anemia but a preferable term according to Wintrobe is simple chronic anemia There is very little alteration in the morphology of erythrocytes in this anemia and it bears a close resemblance to that observed in chronic debilitating disease of several types including disseminated tumors and chronic renal failure

Among infections in which anemia may become very prominent is subacute bacterial endocarditis In the vast majority of instances the anemia is only moderate and is not a serious clinical problem Brucellosis tuberculosis prolonged suppuration etc are also regularly accompanied by mild anemia *The decrease in circulating erythrocytes in* chronic infection apparently results from a combination of depression of the bone marrow and a shortened life span of the red cells One of the earliest changes noted in infection is a reduction in plasma iron content and in serum iron binding capacity This cannot be influenced by the administration of iron whether given in the usual form or as transfused erythrocytes There is delay in the incorporation of labeled iron into erythrocytes and this is mirrored by the clinical observation that individuals with chronic infection are unable to respond to such stimuli as bleeding or an acute hemolytic episode with an outpouring or reticulocytes Indeed the response of patients with pernicious anemia to therapy with vitamin B_1 may be interrupted by an intercurrent infection Other chemical changes observed in the course of the anemia of chronic infection include elevation of serum copper elevation of erythrocyte protoporphyrin and an increased excretion of coproporphyrin There is usually no evidence of increased hemolysis in the form of elevation of urobilinogen or of serum bilirubin but measurement of the life span of erythrocytes in chronic infection has regularly demonstrated a shortening At the present time the only definitive treatment for the anemia of chronic infection is control of the infectious process itself With convalescence there is prompt correction in the hematologic defect

Changes in Platelets

Thrombocytopenia has been observed in a large number of infectious diseases particularly those accompanied by bacteremia The mechanism of the reduction in circulating platelets is not known but may be sequestration in areas where there has been damage to endothelium Purpura is a relatively common manifestation of severe bacterial infections such as meningococcemia and bacterial endocarditis but the relative role of thrombocytopenia capillary fragility and other factors in these conditions remains to be worked out

A lowered number of platelets although not a reduction to levels that might be expected to lead to significant bleeding is observed with great regularity when counts *are made in patients with many different* types of infectious disease including typhoid the rickettsioses the viral exanthemata subacute bacterial endocarditis and infectious hepatitis

Whether the ability of the bone marrow to produce platelets is actually impaired in the course of any of these infections is a question which has not been investigated It is probable that occasional instances of secondary thrombocytopenic purpura are attributable to hypersplenism in the course of chronic infections but this seems to be rare

WEAKNESS AND MALAISE

Patients with acute or chronic infectious disease complain of a variety of unpleasant *somatic sensations These include weakness* fatigability anorexia generalized aching etc While a patient may attempt to describe his symptoms in many ways one ordinarily has only to look at him to realize that he is miserable and uncomfortable beyond his ability to vocalize or to localize the seat of his complaints

Despite the great frequency of these ill defined manifestations of illness surprisingly little is known about the basic mechanisms involved The manifestations are in no way peculiar to infection and indeed many of

them occur in endocrinopathies and even in purely psychiatric disorders The present discussion will be confined to certain aspects of muscle function and to problems of convalescence

Muscle Weakness in Infectious Diseases

When the term weakness is used by a patient to describe his symptoms it is necessary to make further inquiry and to differentiate true loss of muscle strength from lassitude and fatigue When weakness can be demonstrated objectively it becomes important to decide whether the weakness is limited to certain muscle groups, in which case one is dealing with local *paresis* or whether the muscle weakness is generalized in which case a proper term is *asthenia* or *myasthenia* With paralysis or paresis, the possibility of viral infection of the nervous system or of postinfectious neurologic complications must be considered

In terms of the effect of the infectious process on muscle tissue itself there is a wide discrepancy between a patient s complaints and objective findings Adams Denny Brown and Pearson have summarized the available information on alterations in skeletal muscle associated with acute and chronic infectious diseases They classify the pathologic changes into 3 groups Zenker s hyaline degeneration muscle atrophy usually secondary to malnutrition and cachexia in chronic infections and focal myositis a relatively rare occurrence

Zenker's hyaline or waxy degeneration is accompanied by no definite clinical manifestations although it is found relatively frequently in severe infections The morphologic changes consist of focal swelling of muscle fibers usually with eventual involvement of the entire fiber In the beginning striations are easily visible but eventually these disappear, leaving a homogeneous eosinophilic hyaline structure which may undergo degeneration or more often is the seat of regeneration as the infectious process subsides This change can occur in typhoid where it was originally described by Zenker but it has been seen in fatal influenza in pneumococcal pneumonia and numerous other fatal diseases The changes are particularly common in the rectus abdominis muscle, but waxy degeneration is also found in the proximal muscles of the pelvis and the shoulder girdle in the diaphragm and in the larger muscles of the trunk Occasionally there is hemorrhage into the belly of the muscle, in which case there may be local pain but the process is ordinarily difficult to correlate with myalgia in the course of infectious disease When the changes are marked as Adams and his colleagues point out the aches and pains of diseases may be attributable, in part to this type of degeneration However the frequency of impaired muscle strength is far greater than is that of well-demarcated Zenker s degeneration and it appears that this type of change in muscle accounts for only a small part of the objective weakness that accompanies infectious diseases The extent of Zenker s waxy degeneration seems to correlate very well with the severity of the infectious process and lesions of this type have been found in diphtheria tuberculosis tetanus cholera typhoid fever, infectious hepatitis smallpox yellow fever and severe staphylococcal and streptococcal infections It is of considerable interest that similar lesions have been found in patients with noninfectious diseases such as disseminated malignant tumors, hepatic cirrhosis etc

Muscle Atrophy In elderly patients with debilitating disease particularly chronic infections one may see atrophy of muscle This is occasionally associated with vacuolation and edema of individual fibers and is probably a result of a combination of disuse the effect of microorganisms and their toxins and muscle atrophy secondary to the polyneuropathy of malnutrition The recognition of this type of muscle disorder is relatively easy because it is accompanied by other evidences of emaciation with disappearance of subcutaneous fat and reduction in muscle mass A characteristic clinical reation is the ridgelike contraction that can be elicited by a sharp blow This so-called *myoedema or idiomuscular contraction* has been believed to be specific for certain chronic infections such as tuberculosis but careful observations have shown that any chronic disease that impairs general nutrition can produce similar changes in muscle The reduction in muscle

strength in this type of atrophy is usually proportional to reduction in muscle size Consequently the strength of these atrophied muscles is sometimes surprisingly good

Focal Myositis Several infections produce specific and relatively characteristic changes in muscle in the form of focal myositis The muscle lesion in leptospiral infections particularly in Weil s disease is undoubtedly responsible for the severe myalgia that characterizes this disease There is very good evidence that it is produced by leptospiral infection of the muscle itself

While it is entirely possible for pyogenic bacteria to produce muscle abscesses this type of lesion is quite rare in the absence of septic embolization or penetrating injuries

The myositis produced by certain strains of clostridia is described elsewhere Myositis as a result of direct action of the infectious agent has been described in tuberculosis syphilis and actinomycosis

Finally it appears likely that inflammation of muscle can accompany certain viral infections in man although the clinical incidence of viral myositis remains to be evaluated by properly controlled studies Viruses of the Coxsackie group are capable of producing significant destruction of muscle fibers in suckling mice and hamsters It has been shown also that Arbor viruses and other neurotropic viruses produce significant muscle lesions in suckling mice but the clinical counterpart of these lesions in man remains to be determined

The occasional instances of myocarditis that complicate viral infections of many types may have their counterpart in focal lesions of skeletal muscle which are ordinarily so insignificant as to remain unobserved Certainly the fact that Coxsackie B viruses can produce fatal myocarditis in infants is of interest in this regard

Lassitude Fatigability and Problems of Convalescence

Lassitude and fatigue are terms often employed to describe the lack of energy experienced by patients with infectious or other diseases in the absence of objective signs of paralysis or myasthenia The frequency of the subjective sensations described by patients as all in 'without pep no ambition no interest being fed up lack of energy languor "listlessness weariness etc stands in striking contrast to the small body of objective knowledge concerning the mechanisms involved

Infection is a relatively infrequent cause of complaints of chronic fatigue The fact that certain low grade chronic infections may be accompanied by manifestations of lassitude and fatigue is indisputable but the frequency of entirely similar manifestations in individuals with no evidence of an infectious process makes it all the more difficult to link infection with these manifestations in causal fashion

Diseases such as brucellosis tuberculosis infectious hepatitis and certain viral infections of the respiratory tract including influenza are more likely to result in a rather prolonged period of debilitation than are other illnesses with more dramatic acute manifestations On the other hand careful study shows clearly the importance of psychological factors in the persistence of symptoms of lassitude and irritability following apparent recovery from infectious diseases In one such study 24 individuals with a history of acute brucellosis were studied several years after recovery from acute illness Eight of the patients had recovered promptly and uneventfully after subsidence of the febrile stage of the disease Among the remaining patients there were 6 who had remained symptomatic for a year or longer after the acute stage of brucellosis but who had subsequently recovered and 10 patients who had had persistent symptoms for 2 to 8 years since the acute febrile stage of brucellosis and were still symptomatic Medically there was absolutely no evidence of any persistent infection Furthermore extensive psychological testing revealed normal intellectual function without evidence of organic brain damage in all subjects However when these patients were evaluated independently by psychological testing and psychiatric interview it became evident that the chronically ill" patient uniformly revealed evidence of emotional disturbance usually in the pattern of depression Indeed a review of the psychological and psychiatric data made it possible for independent observers to classify each patient without prior knowledge of the

them occur in endocrinopathies, and even in purely psychiatric disorders The present discussion will be confined to certain aspects of muscle function and to problems of convalescence

Muscle Weakness in Infectious Diseases

When the term weakness is used by a patient to describe his symptoms it is necessary to make further inquiry and to differentiate true loss of muscle strength from lassitude and fatigue When weakness can be demonstrated objectively, it becomes important to decide whether the weakness is limited to certain muscle groups in which case one is dealing with local *paresis* or whether the muscle weakness is generalized in which case a proper term is *asthenia* or *myasthenia* With paralysis or paresis the possibility of viral infection of the nervous system or of postinfectious neurologic complications must be considered

In terms of the effect of the infectious process on muscle tissue itself there is a wide discrepancy between a patient s complaints and objective findings Adams Denny Brown and Pearson have summarized the available information on alterations in skeletal muscle associated with acute and chronic infectious diseases They classify the pathologic changes into 3 groups Zenker s hyaline degeneration muscle atrophy usually secondary to malnutrition and cachexia in chronic infections and focal myositis a relatively rare occurrence

Zenker's hyaline or waxy degeneration is accompanied by no definite clinical manifestations although it is found relatively frequently in severe infections The morphologic changes consist of focal swelling of muscle fibers, usually with eventual involvement of the entire fiber In the beginning striations are easily visible but eventually these disappear leaving a homogeneous eosinophilic hyaline structure which may undergo degeneration or, more often is the seat of regeneration as the infectious process subsides This change can occur in typhoid where it was originally described by Zenker but it has been seen in fatal influenza in pneumococcal pneumonia and numerous other fatal diseases The changes are particularly common in the rectus abdominis muscle, but waxy degeneration is also found in the proximal muscles of the pelvis and the shoulder girdle in the diaphragm and in the larger muscles of the trunk Occasionally there is hemorrhage into the belly of the muscle in which case there may be local pain but the process is ordinarily difficult to correlate with myalgia in the course of infectious disease When the changes are marked as Adams and his colleagues point out the aches and pains of diseases, may be attributable in part to this type of degeneration However the frequency of impaired muscle strength is far greater than is that of well-demarcated Zenker s degeneration and it appears that this type of change in muscle accounts for only a small part of the objective weakness that accompanies infectious diseases The extent of Zenker s waxy degeneration seems to correlate very well with the severity of the infectious process, and lesions of this type have been found in diphtheria, tuberculosis tetanus cholera typhoid fever infectious hepatitis smallpox yellow fever and severe staphylococcal and streptococcal infections It is of considerable interest that similar lesions have been found in patients with noninfectious diseases such as disseminated malignant tumors hepatic cirrhosis etc

Muscle Atrophy In elderly patients with debilitating disease particularly chronic infections one may see atrophy of muscle This is occasionally associated with vacuolation and edema of individual fibers and is probably a result of a combination of disuse, the effect of microorganisms and their toxins and muscle atrophy secondary to the polyneuropathy of malnutrition The recognition of this type of muscle disorder is relatively easy because it is accompanied by other evidences of emaciation with disappearance of subcutaneous fat and reduction in muscle mass A characteristic clinical reation is the ridgelike contraction that can be elicited by a sharp blow This so-called *myoedema* or *idiomuscular contraction* has been believed to be specific for certain chronic infections such as tuberculosis but careful observations have shown that any chronic disease that impairs general nutrition can produce similar changes in muscle The reduction in muscle

measles vaccine was followed by varying periods of cutaneous nonreactivity with a gradual reappearance of the ability to show a positive skin test

CONCLUSION

This summary of some of the systemic manifestations to infectious diseases has laid particular emphasis on the reactions of man to invasion by pathogenic microorganisms The great frequency of infectious diseases and the manifestations of illness that have been mentioned in this chapter stand in striking contrast to the relative paucity of information about the physiologic alterations underlying both the objective and the subjective changes that are common to many infections There is perhaps no more fruitful field for future investigation than the re-examination of these common responses with a view of gaining some understanding of the basic mechanisms responsible for them and hopefully the development of methods for their control

clinical course of his disease Thus the emotional disturbance as manifested by a chronic symptomatology in these individuals was not entirely a result of the bacterial disease but was closely related to the personality structure of the individual at the time of the acute illness

A prospective study carried out by obtaining psychological information on a closed population before the onset of an epidemic of viral influenza revealed that the *occurrence of prolonged convalescence could* be predicted Among a group of 600 individuals on whom data were obtained there were 26 documented instances of influenzal infection The symptoms of acute influenza were the same in all patients However 14 of them reported complete recovery within 14 days whereas in the remaining 12 symptoms of tiredness weakness insomnia headache anorexia etc persisted for more than 3 weeks Every individual in whom symptoms persisted showed a pattern of response in the psychological tests characteristic of depression prone individuals Since the psychological data were obtained prior to illness the emotional state or attitude was not secondary to infection but existed prior to the onset of acute illness and was a most significant factor in delaying symptomatic recovery (Imboden)

Miscellaneous Changes Associated With Infectious Disease

A variety of systemic alterations can be mentioned briefly It is not surprising that infectious diseases both acute and chronic, may interfere with general nutrition due to both reduced intake of food and increased metabolic rate Even in individuals with localized suppuration there may be striking weight loss Loss of 25 to 40 pounds within a period of 4 weeks by patients with pleural empyema or chronic lung abscess is not unusual

Acute changes in electrolytes may occur in many infectious diseases In pneumococcal pneumonia and in *tuberculosis, there is depression* in the urinary excretion of sodium and of chloride and there may be a reduction in the serum concentration of these ions Especially in individuals with tuberculosis the level of serum sodium seems to be low and despite administration of large amounts of fluid and electrolyte it is not possible to restore serum levels to the normal range for healthy individuals With response to specific antimicrobial therapy the patient s electrolyte pattern promptly returns to normal

It is not surprising that acute infections stimulate adrenal cortical function the increase being mediated through the pituitary There may also be a mild increase in thyroid function concomitant with the increase in *metabolism that occurs with elevation of* body temperature

Of considerable importance is the effect of bacterial or viral infection on certain hormonal disorders Perhaps the outstanding example of this is the profound worsening of diabetes mellitus that occurs in the presence of infection The insulin requirement in these patients is enormously increased and diabetic acidosis *with coma is* more likely to be precipitated by infection than by any other single factor excepting the omission of insulin by the diabetic patient As is well known, crisis in patients with Addison s disease is often precipitated by viral or bacterial illness and in the past many patients with adrenal insufficiency succumbed to intercurrent infection At the present time, with better control of Addison s disease through the use of complete replacement therapy this is a less serious clinical problem

Finally mention may be made of the effect of certain viral diseases on the nephrotic syndome and on the ability of the skin to react to allergens Children with nephrosis often will undergo spontaneous diuresis as a result of infection with *measles or* with the virus of sandfly fever The mechanism of this induction of remission is entirely unknown but it appears to depend on a specific property of only a few viruses Individuals recovering from measles often undergo a transient period during which they will not react to the subcutaneous injection of tuberculin or of other substances such as *codeine This period of cutaneous* "anergy is variable but may last for several months That it is closely related to infection by the measles virus is indicated by recent studies in volunteers known to react cutaneously to certain allergens *The administration of live*

THE INDIGENOUS BACTERIA AND FUNGI

The following listing is limited to the more clearly recognized species found commonly in the absence of significant disease in one or more loci of the normal flora of man Pathogenic associations are noted Sites fre quencies of occurrence and concentrations are considered in a later section

Cocci

Staphylococci Among gram positive mass forming cocci the principal members of the indigenous biota are the potentially patho genic (coagulase positive) *Staph aureus* (*Staph pyogenes*) and the coagulase negative *Staph albus* Tetrad (*Gaffkya tetragena*) and packet (*Sarcina lutea*) forming cocci have also been recovered from the human mouth (Pike 1962) but less regularly *Staph albus* appears to be a typical am phibiont

ANAEROBIC MICROCOCCI The least ob scure members of this poorly studied group are *Staphylococcus anaerobius* (Foubert and Douglas 1948) a nonfermenting catalase former and *Micrococcus niger* which forms gas and a black pigment

Streptococci Group A *Str pyogenes* and *Diplococcus pneumoniae* have been recovered often enough from healthy persons to be thought of as indigenous However the char acteristic indigenous streptococci fall into the enterococcus and the viridans groups

ENTEROCOCCI are characterized by the group D polysaccharide They are extraor dinarily resistant to environmental influences (see Buttiaux and Mossel 1961) Most spe cies of enterococci grow at both 10 and 45 at pH 9 6 in 6 5 per cent NaCl and in 40 per cent bile and withstand 60 temperature for 30 minutes They are generally resistant to penicillin The commonest species in man are *Str faecalis* and *Str faecium* which are distinguished by failure of the latter to reduce litmus milk or to grow in 1 2 500 potassium tellurite and of the former to ferment ara binose Varieties of *Str faecalis* which yield β hemolysis (*Str zymogenes*) or liquefy gelatin (*Str liquefaciens*) are also common (see Papavassiliou 1962 Colobert *et al* 1962 Defayolle and Colobert 1962)

Enterococci are amphibiotic in man and animals without clearly defined primary pathogenicity but are nevertheless capable of causing disease in some situations notably subacute bacterial endocarditis and urinary tract infections An attempt by Deibel and Silliker (1963) to confirm experimentally in human volunteers early suggestions that en terococci may be implicated in food poison ing was unsuccessful

VIRIDANS STREPTOCOCCI are a heterogen ous group of amphibionts principally non hemolytic sometimes greening on blood They lack either D or A polysaccharides (or the group N antigen of the lactic strepto cocci) The Lancefield polysaccharides C E F G H O K and M have been identified in streptococci that probably belong in the viridans groups Williams (1956) for ex ample found that 58 per cent of 103 strains of *Str salivarius* reacted with group K anti sera and considered this and other antigens of this class (H and E) to be nonspecific (See also Ottens and Winkler 1962 Rifkind and Cole 1962 Stewart and McKeever 1963)

Str salivarius (syn *Str hominis*) the most clearly defined viridans streptococcus is characterized by levan production and large mucoid colonies on 5 per cent sucrose agar It is usually nonhemolytic on blood agar grows at 45 but not at 10 ferments inulin salicin and esculin and acidifies and coagulates litmus milk

Str mitis The remaining members of the viridans group although various may be grouped pending more adequate classifica tion under the specific name *mitis* All are levan and inulin negative and do not grow as mucoid colonies on sucrose agar but some form dextran from sucrose These are char acteristically but not invariably greening on blood agar Streptococci of subacute endo carditis fall largely in this group but attempts to define a pathogenic species (so-called *Str sanguis* or *Str s b e*) are not considered valid The encapsulated *Streptococcus MG* used diagnostically in primary atypical pneu monia may be a distinctive antigenic type

PEPTOSTREPTOCOCCUS Anaerobic strep-tococci some of which become adapted to aerobic growth have been reclassified as a separate genus by Breed *et al* (1957) Little

THEODOR ROSEBURY, D D S

Bacteria Indigenous to Man

From the moment of birth and throughout life man is exposed to microorganisms The resultant effects may take a seemingly continuous range of forms depending on the distinctive reactivity of the microorganisms Many true saprophytes fail to maintain themselves on human tissues But given suitable partial adaptation of microbe to host species the resultant is likely to include a manifest host response recognizable as overt disease Pathogens may achieve equilibrium with the host either from the start (as in healthy carriers of pneumococci or hemolytic streptococci) or after an initial upset as with a wide and familiar range of infective diseases As discussed in Chapter 2 there is a continuous spectrum from the imminent or potential pathogenicity known as latency through apparently permanent neutrality (the resultant of the interaction being undetectable) to symbiosis The word commensalism is often applied to this intermediate range but like other terms that grew out of an early and necessarily rigid interpretation of the germ theory in which the focus was sharply on disease and a simple cause and effect relationship commensalism implies a passivity that now seems to be unsophisticated A better term borrowed from vertebrate zoology may be amphibiosis —including both symbiosis and antibiosis (or pathogenicity) or anything between the two

The indigenous bacterial biota of man may thus be characterized as occupying a band of a continuous spectrum between saprophytes and pathogens typically neither but merging with both In the middle of the band the biota consists of obligate parasites which in pure culture lack obvious or easily demonstrable pathogenicity Some of them are distinctive species known to occur only in this habitat The greater variety are closely related to the more characteristic freely communicable bacterial pathogens for man On the other hand animal pathogens that infect man aberrantly and are not usually communicated from man to man like *Pasteurella* or *Brucella* do not have relatives in the indigenous biota These circumstances suggest an evolutionary adaptation of both participants from pathogenicity toward amphibiosis

In this context the word infection may need redefinition All that it implies is an interaction of a host organism with a smaller self replicating agent This definition is in line with the now generally held view that infection can occur without disease which is only one of its possible consequences At the end of the spectrum in which the microorganisms concerned are most highly adapted to man as host—the true amphibionts—the relationship is a balanced and stable one Nevertheless the balance still may be upset with resulting damage to either parasite or host

The following account of the indigenous biota including the sections on its distribution and significance and on its nonpathogenic effects is abridged with additions from the more recent literature from Rosebury (1962)

fermenti with smooth to intermediate colonies less actively saccharolytic and having intermediate acidogenicity and (5) *L brevis* rough with short to medium bacilli fermenting a wider range of test carbohydrates than the preceding but producing relatively little acid

Corynebacterium These principally or exclusively catalase positive gram positive nonmotile rods often pleomorphic include the characteristic diphtheroids of mucous membranes The traditional simple criterion of fermentation of glucose and sucrose separates the nonfermenting *C hofmanni* (*C pseudodiphtheriticum*) and the fermentative *C xerosis* from pathogenic forms (*C diphtheriae* and others) which ferment only glucose However nontoxigenic *C diphtheriae* and otherwise nonpathogenic glucose fermenters are well recognized and all 3 fermentation patterns appear commonly among indigenous species *C haemolyticum* and other aerobic catalase negative forms are probably more appropriately classified as streptococci or in other genera (see Zinneman and Turner 1963)

Corynebacterium acnes and other anaerobic or micro aerophilic diphtheroidlike bacteria constitute an ill-defined group members of which have been classified variously as *Lactobacillus Actinomyces Propionibacterium* and in several less familiar genera The definition of *Lactobacillus* given above separates that group It may be feasible to include catalase negative anaerobic forms in the genus *Actinomyces* as noted below Among the remaining members of this group the catalase positive anaerobe *C acnes* (or *Propionibacterium acnes* see Moore and Cato 1963) is indigenous to skin and widely distributed in other locations both amphibiotically and saprophytically Several studies have established a clear distinction between this organism and the anaerobic actinomycetes Bouisset *et al* (1963) have reported differences in DNA base ratios between the aerobic diphtheroids and the anaerobes

Actinomyces If the generic name *Actinomyces* is limited to anaerobic catalase negative gram positive bacilli with a tendency to branch it would include 2 groups (1) those associated with actinomycosis the *bovis israelii* forms and (2) *A bifidus* more commonly called *Lactobacillus bifidus* but excluded from the latter genus by several groups of workers in recent years

A distinction between two species of the first group *A israelii* and *A bovis* now seems unequivocal on the basis of differences in cell wall composition and serology (King and Meyer 1963) *A israelii* is a rough amphibiotic form which sometimes causes actinomycosis in man *A bovis* is smoother more diphtheroidlike and is found typically in cattle

Actinomyces bifidus (*Lactobacillus bifidus*), although recognized since the turn of the century as the predominating bacterium of the feces of breast fed babies remains inadequately defined and classified Studies especially during the 1950 s which have established the characteristics of the lactobacilli generally have excluded the bifidus forms both morphologic and metabolic findings have pointed to a relationhip to *A israelii* Attempts to subdivide the bifidus group have yielded inconsistent results The occurrence of a variety *pennsylvanicus* (Gyorgy *et al* 1954) which requires for growth a mucopolysaccharide fraction of blood group substance found in human milk and colostrum has been suggested as explaining the bifidus nursling relationship but the *A bifidus* found in nursling feces has simpler nutritive requirements not including the *pennsylvanicus* factor and it is possible that human milk selects *A bifidus* by inhibiting coliforms and enterococci rather than by direct stimulation

Leptotrichia General agreement seems to have been reached in the early 1960 s that this generic name and the single identified species name *L buccalis* be limited to a bacterium long recognized as an amphibiotic resident of the human mouth a rather thick unbranched gram positive organism growing as long rods or filaments anaerobic catalase negative homolactic (final pH approximately 5 0) forming typical translucent rough colonies on enriched agar Irregularities of morphology and a tendency to decolorize in the gram stain have led to confusion between this organism and *Fusobacterium* which is however morphologically and biochemically distinct

Bacterionema matruchotii (syn *Lepto*

attention has been paid to them in recent years and they are in need of reconsideration These streptococci have been associated with endogenous anaerobic mixed infections including a form of puerperal fever studied especially in the 1930s wound and other infections in which bacteroides were also implicated and the so-called fusospirochetal infections as detailed in a later section Although additional species names are used the following represent the principal ones

P putridus a strict anaerobe gas forming and fetid forms large volumes of gas, principally CO from glucose fructose and maltose but only in the presence of S-containing compounds (Hare *et al* 1952) Also formed are NH_3 H S and formic butyric and acetic acids The cocci tend to be large and pleomorphic

P evolutus which acquires oxygen tolerance and *P micros* a strict anaerobe both fail to produce gas or odor (see Hare *et al* 1952 Mergenhagen and Scherp 1957)

Neisseria *N meningitidis* like group A streptococci and pneumococci has frequently been found in healthy carriers in whom it may achieve amphibiotic status However the more typically indigenous members of *this genus are characteristic amphibionts* The generic name should be limited to aerobic oxidase positive gram negative cocci Principal species are *N catarrhalis* unpigmented no acid from carbohydrates *N sicca* unpigmented ferments glucose maltose fructose and sucrose (but see Berger 1961a b) resembles the meningococcus but grows more abundantly and at 22° it forms a dry rough colony and is antigenically distinctive *N pharyngis* chromogenic (forming greenish yellow colonies) fermentative with strain variations antigenically heterogenous and *N mucosa* resembling *N sicca* but encapsulated mucoid and serologically distinct

Pike *et al* (1962) have suggested that nonpathogenic neisseria including named strains from various sources and fresh isolates from the mouth all could be grouped as *N pharyngis* and *N catarrhalis* of which the former was the more common For a review of nonpathogenic neisseria see Berger (1963)

Veillonella. Although several species of strictly anaerobic gram negative cocci are thought to exist only one *V alcalescens* (syn *V gazogenes Micrococcus lactilyticus*) has been identified clearly (see e g, Rogosa *et al* 1961) This widely distributed amphibiont is a small spherical mass forming coccus which may be gram positive during the first few hours of growth but is uniformly gram negative after 12 hours It fails to ferment sugars but ferments lactate and other *intermediate* products of hexose breakdown producing propionic and acetic acids with CO and H in large amounts, accompanied by a rise in pH Many biochemical studies of this organism have been published (see e g McCormick *et al* 1962a b Whiteley and McCormick 1963 Woolfolk *et al* 1962) *V alcalescens* is apparently not specifically pathogenic It contains endotoxin (Mergenhagen *et al* 1962 1963)

Gram positive Bacilli

Lactobacillus The generic name *Lactobacillus* is coming to be limited to catalase negative gram positive nonmotile rods that *grow aerobically and ferment* carbohydrates actively either homofermentatively to lactic acid or heterofermentatively to lactic acid and other products including CO (The anaerobic *L bifidus* is included under *Actinomyces* see below) Many species of lactobacilli inhabit the mucous membranes Of these only one *L acidophilus* is obligately parasitic the others including the commonest and most numerous indigenous species are widely distributed in nature Some of these organisms by virtue of their high acid production may be a significant factor in dental caries They are thought to play a symbiotic role in limiting the flora of the vagina

Among indigenous *homofermentative* lactobacilli the commonest species found are (1) *L casei* with smooth colonies and curved bacilli growing at 15° and irregularly at 45° actively acidogenic (2) *L acidophilus* rough with long bacilli growing at 45° but not at 15° less actively saccharolytic and acidogenic and (3) *L plantarum* smooth with short straight bacilli growing at 15° but usually not at 45° actively saccharolytic and acidogenic The two commonest *heterofermentative* species are (4) *L*

cific or variety names (*Bacterium* etc) *anitratum* and *glucidolytica* This organism is also known by the notebook code designation B5W

Although the literature on these microorganisms deals predominantly with their occurrence in disease they also reside on normal mucous membranes The principal sites in which members of the group have been found normally are the nose the vagina and the conjunctiva Pathologically they have been recovered from a wide range of sites and conditions The conditions attributed to them include for all 3 species conjunctivitis and meningitis and especially for penicillin resistant forms (*Mima* spp) gonorrhealike urethritis Attempts to demonstrate experimental pathogenicity have been successful in some instances but in general only with massive doses suggesting a typical amphibiotic behavior

Pseudomonas Alcaligenes A large group of gram negative strictly aerobic saprophytic bacilli some of which are pigment formers and manifest obligately aerobic glycolysis (*Pseudomonas*) while others are achromogenic and may be nonglycolytic (*Achromobacter*) are linked in part because variants of the first group may lose or fail to show the distinguishing features mentioned Motility due to polar flagella is characteristic of the first group and is variable in the second The most important strains are *P aeruginosa* (*Bacillus pyocyaneus*) and *Alcaligenes* (*Achromobacter*) *faecalis*

Pseudomonas aeruginosa is identified by the formation of water soluble fluorescent bluish green pigments (the blue green phenazine pigment pyocyanin and the greenish yellow fluorescein) It is proteolytic and forms acid from glucose only when grown with free access to air Other distinguishing features are oxidation of potassium gluconate a rapidly positive test for cytochrome oxidase and rapid breakdown of arginine Along with staphylococci *Candida albicans* and a few other species this micro-organism has become of greater pathogenic importance during the antibiotic era (see Flynn and others 1963) The increased frequency of pseudomonas disease is based at least in part on the widespread distribution of this organism and on its ability to develop resistance to antibiotics Experimental pathogenicity has been demonstrated under conditions typical for amphibionts entailing e g injection of 10^8 or more organisms intraperitoneally into mice or pretreatment with x radiation

Alcaligenes faecalis is distinguished from *Mima polymorpha* which it resembles biochemically by being consistently bacillary and gram negative growing regularly on simple nutrient agar and being frequently motile It does not attack glucose or other carbohydrates but grows in a medium containing only lactate asparagine and salts It is found in feces and appears uncommonly in a variety of pathologic situations (see Sherman *et al* 1960)

Vibrio Aerobic members of this genus recovered from feces e g *V alcaligenes* and *V percolans* have been found to be indistinguishable from *Alcaligenes faecalis* or from pseudomonads

Haemophilus Of the nutritionally fastidious aerobic gram negative bacilli requiring phosphopyridine nucleotide (V factor) or hemin (X) or both *H influenzae* and the hemolytic *H haemolyticus* which require both are characteristically found in the healthy mouth and upper respiratory tract as are the corresponding forms that require only V factor *H parainfluenzae* and *H parahaemolyticus* The indigenous influenza bacillus proper is usually rough and lacks the *b* capsular antigen of the typical pathogen for man but probably possesses endogenous pathogenicity

H aegyptius (the Koch Wells bacillus) antigenically distinct from non type specific *H influenzae* has been found in the healthy conjunctival sac as well as in conjunctivitis Two other species *H vaginalis* and *H aphrophilus* are both probably better classified in other genera Neither species appears to require X or V factors *H vaginalis* associated with vaginitis but probably indigenous to the area (see Dunkelberg *et al* 1962) has been classified as *Corynebacterium vaginale* principally on morphologic grounds but differs from diphtheroids in being catalase negative (Zinnemann and Turner 1963) *H aphrophilus* is a little studied gram negative aero

TABLE 1 PRINCIPAL DISTINGUISHING CHARACTERISTICS OF *Moraxella Mima**

Neisserialike short rods or coccal forms in pairs or short chains with some longer rods and filaments gram negative to gram amphophile aerobic anaerogenic Indole and Voges Proskauer negative Usually nonmotile encapsulated and methyl red negative

	Serum Required for Growth	Growth in Defined Media	Liquefaction of Serum or Gelatin	Acid from Glucose	H S Formed	NO_3 Reduced to NO	Oxidase	Sensitive to Penicillin

* (From Rosebury [1962] McGraw Hill Book Co)

trichia dentium) is another oral bacterium sometimes confused with *L buccalis* but clearly distinguished since 1958 This organism is aerobic catalase positive and consistently gram positive forming filaments often with elongated swellings and sometimes showing branching A relationship to *L buccalis* and to *Nocardia* was suggested by Davis and Baird Parker (1959b) on the basis of the finding of DAP in the cell wall Common antigens have been found by complement fixation with *Nocardia Mycobacterium Corynebacterium* and *Actinomyces* but not with *Lactobacillus* (Schmidt and Richardson 1962) Sibal and co workers (1962) using acid soluble antigens in tube precipitin and gel diffusion studies found little or no cross reaction with *L buccalis Actinomyces* spp *Nocardia asteroides* or *Lactobacillus* spp

Mycobacterium There are suggestions that several species of mycobacteria other than true tubercle bacilli occur in man frequently enough in the absence of symptoms to be thought of as indigenous These include *M smegmatis* present in external genital secretions according to early literature and other members of the so-called atypical or unclassified mycobacteria (see Chap 21)

Clostridium *C perfringens* (type A) is found commonly in human feces *C tetani* common in animal feces has been recovered only irregularly in man More typical soil clostridia have also been found occasionally in man but as with members of the genus *Bacillus* under similar circumstances may probably be dismissed as transients

GRAM NEGATIVE AEROBIC BACILLI
(See also Chap 25)

Enterobacteria The easily grown aerobic gram negative rods although outnumbered in the intestinal tract by anaerobes of other genera are the best known of indigenous bacteria

Moraxella and Mima Certain gram negative aerobic bacilli on which a large literature has been accumulating are distinguished by neisserialike characters coccal as well as bacillary (and filamentous) forms a tendency to gram variability intracellular occurrence pathologically in spinal fluid or genitourinary exudates and a gradient of properties ranging from oxidase positivity and penicillin sensitivity to the reverse The former are also generally glucose nonfermenters whereas the oxidase negative penicillin resistant forms tend to be aerobically glycolytic Variation from apparently obligate parasitism to saprophytism is correlated with decreasingly exact ing nutritive requirements The principal features of the 3 species defined tentatively pending more adequate taxonomic study of the group are given in Table 1

Moraxella lacunata (the Morax Axenfeld bacillus) here includes *M duplex* and its variants *Mima polymorpha* is considered to be a transitional group some strains of which are oxidase and penicillin positive similar strains giving negative reactions constitute the *Moraxella lwoffi* of French workers *Mima vaginicola* the glycolytic group appears under a variety of names including the genera *Herellea Achromobacter* and *Acinetobacter* as well as *Moraxella* and the spe

appearance of tufts of flagella in light microscopy has given rise to the apparently erroneous practice of considering this organism to be a protozoan (*Selenomonas sputigena*) *S sputigenum* appears to be an unusually fastidious anaerobe difficult to cultivate on agar surfaces but growing well in thioglycollate broth under petrolatum

Vibrio sputorum is a small usually curved polar flagellated gram negative organism with pointed ends Its motility is rapid darting often in an elliptical course and characterized by stops sometimes with reversal of direction It grows anaerobically on enriched agar surfaces or as stab cultures in semi solid agar but poorly in broth It is non saccharolytic

Butyrivibrio fibrosolvens a small motile gram negative anaerobe originally isolated from the rumen was recovered from high dilutions of human feces in 2 of 7 trials by Brown and Moore (1960) who also provided evidence that the organism may participate in fermentation in the human intestine producing butyric and other fatty acids

SPIROCHETES
(See Chap 24)

These flexible highly motile nonflagellated microorganisms include anaerobic forms indigenous to mucous membranes Usually sparse in the absence of inflammatory disease they may occur in enormous numbers under many pathologic conditions Since gingivitis commonly mild or localized is seldom entirely absent spirochetes can be demonstrated nearly universally best at the bottom of the gingival crevice or pocket

The amphibiotic spirochetes have been cultivated principally by variations of the Noguchi method in the depths of enriched agar media Means for isolation from surface colonies have been proposed in recent years (Socransky *et al* 1959 Hardy *et al* 1963) The validity of the current classification of the indigenous spirochetes is doubtful Cultures derived from different sites such as mouth intestine and genitalia, have been arbitrarily given different names The evidence suggests that both of the anaerobic parasitic genera *Treponema* and *Borrelia* are represented among indigenous forms but until more reliable information is at hand only a single species of each need be named

Treponema dentium (*T microdentium* etc) is a pallidumlike spirochete tightly wound single contoured capable of active motility with rapid rotation darting progression and flexing movements suggesting greater rigidity than do the typically soft undulations of *T pallidum* Listgarten *et al* (1963) found in electron micrographs an axial filament made of 2 fibrils (*T pallidum* has 3) approximately 150 Å in diameter lying between an external envelope and the protoplast The organisms are usually actively proteolytic but many cultures do not ferment carbohydrates They appear to be very fastidious both in their nutritive requirements (see Pillot 1962) and in their need for anaerobiosis Their pathogenic proclivities remain poorly defined These forms rather than *Borrelia* spp seem to be most consistently associated with fusospirochetal disease but most attempts to demonstrate experimental pathogenicity have yielded at most nontransmissible disease (see Hampp and Mergenhagen 1961 1963)

Borrelia refringens These loosely wound indigenous spirochetes have been defined only provisionally The name assigned by Schaudinn and Hoffmann in 1905 to a genital form (which they distinguished from the spirochete of syphilis) has priority Forms with single contours (called *B vincentii* in the mouth) and double contours (*B buccale*) are probably variants of one species Many other synonyms have been used The pitch (crest to-crest distance) of *B refringens* is usually more than twice that of *T dentium* (approximately 2 5 to 4 microns as compared with 1 2 microns) The coils are regular when the spirochetes are viable and active Swain (1955) gave the following measurements from electron micrographs thickness 0 23 to 0 64 micron average 0 42 micron 8 to 11 axial fibrils 200 Å wound helically around the helical protoplast In active motion these spirochetes spin rapidly and seem to stretch their coils almost taut as they move in straight lines they may stop intermittently relax their winding and reverse their direction Slower movements are less characteristic These spirochetes stain more easily with aniline

bic rod which has been found together with *Actinomyces israelii* in actinomycosis as has the equally obscure so called *Actinobacillus actinomycetemcomitans* Both organisms have also been found under normal conditions The two forms appear to be distinct (see King and Tatum 1963)

Gram negative Anaerobic Bacilli and Spirilla
(See also Chap 32)

Bacteroides, Fusobacterium A large and varied group of amphibiotic obligately anaerobic gram negative rods some of which are fusiforms or filamentous or highly pleomorphic have been classified under many names, both generic and specific but are grouped here pending further study into two related genera and a restricted range of species The bacteroides are probably the most numerous organisms in adult human feces (see Zubrzycki and Spaulding 1962) On the other hand Haenel (1961) made no mention of gram negative anaerobes in reporting on 50 analyses of feces of 21 healthy adults According to this worker the predominant organism in feces (10^9 to 10^{10} per Gm) is a facultatively anaerobic lactobacillus They are usually nonfusiform but range in morphology from regular rods to filaments and highly pleomorphic forms All but one species (*B serpens* one of the least understood of this neglected group) are nonmotile The fusobacteria include one motile and one nonmotile species

Bacteroides fragilis probably the commonest species in feces is nonpleomorphic saccharolytic (pH in glucose 4 6 to 5 4) and penicillin resistant It usually requires enriched media *B funduliforms* (*B* [*Sphaerophorus*] *necrophorus*) the highly pleomorphic form most commonly implicated in disease is a moderately weak fermenter (pH 5 6 to 6 5) grows in simple media after isolation and reacts variably to penicillin It produces H S and NH_3 and a predominantly butyric fermentation *B nigrescens* (*B melaninogenicus*) is a distinctive species or group that forms a black pigment (a hematin derivative) from hemoglobin after 3 to 5 days growth These pigment formers have been intensively studied in recent years under the hypothesis that they may be significant contributors to certain mixed anaerobic infections as noted below Sawyer *et al* (1962) found that all of 31 strains actively hydrolyzed collagen and gelatin and produced H S All required or were stimulated by hemin some strains required menadione or related naphthoquinones Wide variation in fermentative activity was observed *B nigrescens* is sensitive to penicillin and to other antibiotics

Bacteroides (*Dialister*) *pneumosintes* is the name assigned to a small gram negative anaerobic bacillus first isolated from the nasopharynx during the 1920 s and said to be filterable through Berkefeld V and N filters A single strain obtained from Prevot was studied by Sonnenwirth (1960) and more recently by Chien-Ching Chen and Cleverdon (1963) Except for its small size the organism seems to be related to *B fragilis* The latter workers established its maximum diameter as 0 4 to 0 6 micron by Millipore filtration

Fusobacterium fusiforme is the typical small nonmotile fusiform bacillus found on normal mucous membranes and in fusospirochetal disease Morphologically it resembles *B funduliformis* but is more clearly spindle shaped and less pleomorphic It differs also in being less acidogenic in glucose (final pH not less than 6 0) in requiring enriched media and in being uniformly sensitive to penicillin This organism has been confused with *Leptotrichia buccalis* from which it differs in morphology and metabolism Confusion with spirilla (e g *S sputigenum* see below) and spirochetes was formerly common *F fusiforme* is easily and clearly separable from both

Fusobacterium girans is a slowly motile nonflagellated gram negative anaerobic fusiform found in the mouth

Anaerobic Spirilla and Vibrios A group of curved or helical flagellated anaerobic bacteria is found in areas of abundant mucous membrane flora and is associated especially with fusospirochetal overgrowths Among these can be distinguished *Spirillum sputigenum* a variable comma shaped S shaped or helical form showing active motility This organism is typically gram negative but may appear to be weakly positive Its flagella are peritrichous but the

of averages (2) the colony count per unit of surface volume or weight given as a range in rounded $\log s_{10}$ and (3) where the preceding data are not available a rougher measure of occurrence or prominence in terms of ± 1+ or 2+ Spaces left blank usually indicate absence of information

In body sites not given in the table the prevailing condition in health is presumably either microbiologic sterility as in blood and tissues or a sparse biota approaching extinction or in passage as in larynx trachea bronchi accessory nasal sinuses esophagus stomach upper portions of the intestinal tract upper urinary and posterior genital tracts and subjacent structures The healthy conjunctiva and anterior urethra also have a scanty flora and the nasal and the vaginal mucous membranes are relatively lightly populated

Microbic colonization begins at birth the first settlers being transferred from the maternal vagina and perineal area to the infant skin mouth nose and oropharynx The characteristic biotas of these and other areas develop later and probably are derived and selected from various environmental sources The character of the amphibiotic relationship and the relative uniformity of the flora in widely scattered persons suggest an origin principally in other human beings

It may be useful to subdivide the indigenous microbiota of man into 3 groups In the first of these (the lower intestine) extraneous pabulum is present in massive amounts and tends to favor the overgrowth of saprophytes (although true amphibionts e g bacteroides still predominate) In the second—the mouth the oropharynx and the vulva—pabulum is relatively abundant enriched either by extraneous material (from ingested food) or accumulated cell debris or both crypts or recesses particularly favor anaerobes The third—the skin—differs in its lower moisture and high lipid contents which tend to select a somewhat different biota It is worth emphasizing that in general strict anaerobes tend to outnumber facultative forms and aerobes usually by a factor of 10 to 100 or more This is true even in skin and in the highly ventilated nasal passages

SIGNIFICANCE OF THE INDIGENOUS BIOTA

Under the usual conditions of exposure man s skin and the mucous membrane lined orifices leading inward directly from it rapidly become populated with a varying but nevertheless characteristic range of microorganisms These are assumed to be in continual interaction with the host and with other species within the biota itself leading to fluctuations in the biota both qualitative and quantitative and to more or less pronounced effects on the host These effects range from beneficial through inapparent to detrimental (See also Dubos *et al* 1963)

NONPATHOGENIC ACTIVITIES

The discernible nonpathogenic effects of the normal flora on the host include (1) nutritional effects resulting from microbial synthesis (2) various interactions between microbiota and host (3) protective effects of latent infection (4) direct and indirect consequences of interactions between the microbes themselves including antibiotic effects and (5) other phenomena that can be recognized either directly or by inference from experimental studies of germ free animals

Germ free animal studies merit more extended discussion than space permits (see Rosebury 1962 and the review by Mickelsen 1962)

Several species of vertebrates have been bred through successive generations in a germ free state Thus the biota is not essential for their continued existence Experiments in which germ free animals have been contaminated deliberately or accidentally have begun to provide much basic information on the effects of the microbiota which will be considered under the following heads

The Indigenous Biota in Host Nutrition Despite the fact that the microbiota is not essential to host life considerable evidence indicates that the normal intestinal flora contributes to host nutrition Some members of the biota especially the nutritionally nonfastidious enterobacteria, synthesize vitamins

dyes, e g, crystal violet than the tightly wound forms they are typically distorted in routine dried films Cultivation of the loosely wound forms has been reported less frequently than of *T dentium*, especially from the mouth Detailed methods that might permit cultivation of *B refringens* apart from the other forms have not been reported Statements as to its nutritional and metabolic characteristics are to be regarded with caution It has been suggested that these loosely wound spirochetes share the elusive pathogenic attributes of the tightly wound forms (Hampp and Mergenhagen 1961)

Fungi
(See also Chap 37)

Nearly all fungi found in man are saprophytes widely distributed in the environment Therefore the separation of indigenous species is more than ordinarily difficult Exceptions appear among yeastlike fungi The association of *Pityrosporum* species (*P ovale* and *P orbiculare*) with the skin may be due to its requirement for fatty acids or glycerol *Torulopsis glabrata* also occurs on the skin and the mucous membranes it is said to require biotin thiamin niacin and pyridoxin for growth at 37 C The dimorphic yeastlike form *Candida albicans* although capable of growing saprophytically seems to be limited in its distribution to parasitic sites Other species of *Candida* namely the closely related *C stellatoidea* and *C tropicalis* may be true amphibionts while still others—*C parapsilosis C krusei C guilliermondi* and *C pseudotropicalis* although saprophytic appear on mucous membranes often enough to be thought of as indigenous *T glabrata* and the *Candida* species can cause experimental disease in mice and have also been implicated in human disease (see e g Hurley and Winner 1962) *C albicans* is evidently the most pathogenic of these forms but even this species causes disease only when the infecting dose is large or when certain abnormal conditions exist for example when the experimental animal has been pretreated with cortisone or x-radiation Prolonged treatment with broad spectrum antibiotics often leads to the appearance of candidiasis in man and also facilitates the establishment of *C albicans* in the mouse intestine (see Sheldon and Bauer 1962)

Certain of the dermatophytes of tinea pedis namely *Trichophyton rubrum T mentagrophytes* and *Epidermophyton floccosum* may be included among amphibionts because of their widespread occurrence on healthy skin of the feet and also because certain aspects of both the naturally occurring disease and of its experimental reproduction in man suggest endogenous infection (see Barlow *et al*, 1961, but also Ajello 1962)

Although *protozoa* are outside the scope of this book, it should be noted that members of this group are indigenous to the human mouth intestine and vagina (see Rosebury, 1962)

Pleuropneumonialike and Related Forms
(See also Chap 35)

The interrelationship between so-called PPLO (pleuropneumonialike organisms), L phase variants of bacteria and bacteria from which the cell wall has been denuded experimentally partially or completely (spheroplasts and protoplasts) is still unsettled For this reason it is inadvisable to apply separate generic and specific names to these forms (Rosebury, 1962) In the present context it may be noted that both PPLO which are not known to revert to bacteria and L forms which are have been recovered from oral pharyngeal anorectal and genitourinary mucous membranes both in health and in disease They are recovered more commonly under pathologic conditions and have been held responsible for disease especially nonspecific urethritis but experimental pathogenicity generally has not been demonstrable

DISTRIBUTION OF THE INDIGENOUS MICROBIOTA

The distribution of species or groups of bacteria and fungi in various sites are summarized in Table 2 Data are given in the table in 3 ways (1) the incidence as a percentage of subjects studied given as a range

of averages (2) the colony count per unit of surface volume or weight, given as a range in rounded $\log_{10}$ and (3) where the preceding data are not available a rougher measure of occurrence or prominence in terms of ± 1+ or 2+ Spaces left blank usually indicate absence of information

In body sites not given in the table the prevailing condition in health is presumably either microbiologic sterility as in blood and tissues or a sparse biota approaching extinction or in passage as in larynx trachea bronchi accessory nasal sinuses esophagus stomach upper portions of the intestinal tract upper urinary and posterior genital tracts and subjacent structures The healthy conjunctiva and anterior urethra also have a scanty flora and the nasal and the vaginal mucous membranes are relatively lightly populated

Microbic colonization begins at birth the first settlers being transferred from the maternal vagina and perineal area to the infant skin mouth nose and oropharynx The characteristic biotas of these and other areas develop later and probably are derived and selected from various environmental sources The character of the amphibiotic relationship and the relative uniformity of the flora in widely scattered persons suggest an origin principally in other human beings

It may be useful to subdivide the indigenous microbiota of man into 3 groups In the first of these (the lower intestine) extraneous pabulum is present in massive amounts and tends to favor the overgrowth of saprophytes (although true amphibionts e g bacteroides still predominate) In the second—the mouth the oropharynx and the vulva—pabulum is relatively abundant enriched either by extraneous material (from ingested food) or accumulated cell debris or both crypts or recesses particularly favor anaerobes The third—the skin—differs in its lower moisture and high lipid contents which tend to select a somewhat different biota It is worth emphasizing that in general strict anaerobes tend to outnumber facultative forms and aerobes usually by a factor of 10 to 100 or more This is true even in skin and in the highly ventilated nasal passages

SIGNIFICANCE OF THE INDIGENOUS BIOTA

Under the usual conditions of exposure man s skin and the mucous membrane lined orifices leading inward directly from it rapidly become populated with a varying but nevertheless characteristic range of microorganisms These are assumed to be in continual interaction with the host and with other species within the biota itself leading to fluctuations in the biota both qualitative and quantitative and to more or less pronounced effects on the host These effects range from beneficial through inapparent to detrimental (See also Dubos *et al* 1963)

NONPATHOGENIC ACTIVITIES

The discernible nonpathogenic effects of the normal flora on the host include (1) nutritional effects resulting from microbial synthesis (2) various interactions between microbiota and host (3) protective effects of latent infection (4) direct and indirect consequences of interactions between the microbes themselves including antibiotic effects and (5) other phenomena that can be recognized either directly or by inference from experimental studies of germ free animals

Germ free animal studies merit more extended discussion than space permits (see Rosebury 1962 and the review by Mickelsen 1962)

Several species of vertebrates have been bred through successive generations in a germ free state Thus the biota is not essential for their continued existence Experiments in which germ free animals have been contaminated deliberately or accidentally have begun to provide much basic information on the effects of the microbiota which will be considered under the following heads

The Indigenous Biota in Host Nutrition Despite the fact that the microbiota is not essential to host life considerable evidence indicates that the normal intestinal flora contributes to host nutrition Some members of the biota especially the nutritionally nonfastidious enterobacteria, synthesize vitamins

in excess of their own requirements, and there is evidence that such microbes contribute to host nutrition by supplying significant amounts of biotin, vitamin K, pantothenic acid pyridoxine and vitamin B_{12} In germ free rats there is striking evidence of a need for dietary vitamin K which is not required by conventional animals (Gustafsson 1959)

Host Biota Interactions Other Than Disease Whenever a given microbic species is found regularly and in appreciable numbers in an indigenous locus it may be assumed that its metabolic activity directly or indirectly influences the host

Observations on germ free animals indicate that the indigenous flora may exert on the host beneficial effects not directly related to nutritional supplementation For example in the absence of an intestinal flora guinea pigs and other animals develop an unusual anomaly cecal distension (see Mickelsen 1962) Skelly *et al* (1962) found that enlargement of the caecum in germ free mice could be corrected by feeding anaerobes isolated from the ceca of normal mice a clostridium or a mixture of two strains of bacteroides Germ free animals are also abnormal in many biochemical activities as well as in their greater susceptibility to infection (references in Rosebury 1962) Phillips and Wolfe (1961) observed spontaneous pneumonic disease of presumed viral origin in germ free guinea pigs which could be cured by feeding autoclaved cecal contents of conventional animals (See also Lev 1961)

Latent Infection Antibody Formation Antibodies have been found in healthy human serum or other body fluids to the following microorganisms listed above as indigenous coagulase positive staphylococci nonhemolytic streptococci lactobacilli actinomyces of the israelii group *E coli* and other enterobacteria *P aeruginosa H influenzae B funduliformis* fusobacteria indigenous spirochetes and *Candida albicans* and other members of this genus The significance of these antibodies is not clear but it is probable that they indicate past invasion and presumably subclinical disease Findings in germ free animals make it likely that such antibodies help to protect the host against further invasion by the microbic species concerned The question has been explored especially in germ free rats in which lymphatic tissue was found to be poorly developed (Thorbecke *et al* 1957) There was an associated marked reduction in serum globulin and in antibody activity Grabar *et al* (1961) found that only small amounts of γ globulin were detectable in germ free rat serum by direct analysis although all major antigenic components in conventional rat serum could be demonstrated by immuno-electrophoresis of anti germ free rat immune rabbit serum However germ free mice have normal levels of antibody to endotoxins of gram negative bacilli presumably in response to antigens present in food and water (Landy *et al* 1962) In some instances germ free animals are susceptible to disease induced by indigenous microorganisms for example *Sarcina lutea* and *Bacillus subtilis* (Taylor 1959) but in other cases they have been contaminated with normal feces without developing disease (Gordon 1959)

Interactions of Indigenous Micro organisms Both cooperative (synergistic syntrophic) and competitive interactions occur among indigenous microbic species and between these and either saprophytic or pathogenic intruders Our knowledge of such interactions is generally meager Their study presents formidable difficulties inherent in the vagaries of population mixtures comprising 2 or more species (see Parker and Snyder 1961 Jameson 1962)

Cooperative interactions (other than genetic exchange) include (1) satellitism the production by one species of a condition (e g a low oxidation reduction potential) or a substance (e g a growth factor) which permits contiguous growth of another species and (2) enzyme sharing e g permitting growth of two species in media inadequate for either alone or yielding a joint product not found in the separate pure cultures For examples see Rosebury (1962) and also Freter (1962)

Competitive interactions probably depend on either or both of two phenomena (1) competition for nutrients and (2) the production by one species of conditions (e g a low pH) or substances (antibiotics) adverse for others Antibiotic effects have been described for the following indigenous species

(1) *Staphylococcus aureus* and other staphylococci against corynebacteria including *C diphtheriae* *Bacillus* spp streptococci including *S faecalis* mycobacteria clostridia other staphylococci and other species (2) Nonhemolytic streptococci especially viridans forms (and pneumococci) acting against a wide range of test species including staphylococci cornynebacteria neisseria and many others among them β streptococci Some of these streptococcal effects are known to be due to H O and some including the α β effect are mutual inhibitions effected by the more against the less abundant species (3) Lactobacilli (in addition to their effects attributable to low pH) inhibit staphylococci enterobacteria and other organisms (4) *Pseudomonas aeruginosa* produces a range of antibiotic substances against *B anthracis* *V cholerae* staphylococci streptococci enteric pathogens and others as well as against *Candida albicans* and other fungi This species also produces *pyocines* analogous to *colicines* (see below) (5) Enterobacteria especially *E coli* have been found to be inhibitory in vitro for *Candida albicans* and *C krusei* and for several bacterial species other than enterobacteria themselves but such antibacterial effects have seldom been striking or easily demonstrable The name *colicines* has been applied to an apparently diverse group of substances produced by certain enterobacteria especially certain strains of *E coli* which are inhibitory in vitro for other enterobacteria frequently for other strains of the producing species often also for *Sh sonnei* Goebel and his co workers (see Goebel and Amano 1959 Hutton and Goebel 1962) have found two colicines (K and V) to be associated with the O antigens of the effector strains The strain specificity of colicines has led to their use in typing enteropathogenic *E coli* and other enterobacteria

PATHOGENIC EFFECTS OF THE INDIGENOUS BIOTA

Endogenous Infective Diseases Some General Principles

The subject to be surveyed here is so varied that no attempt can be made to cover it completely Both the idea that indigenous micro-organisms may participate in disease in the presence of predisposing conditions and the term applied to such disease endogenous infections seem to have originated with Escherich in 1889 Although the idea has found support in relation to particular diseases and seems never to have been abandoned it has had a discontinuous history The apparent difficulty that such processes violate an unstated corollary of Koch s first postulate—the alleged causative agents being found in health as well as in disease (the postulates are reviewed in Editorial 1961) and difficulty with the third postulate—isolated pure cultures are nearly always nonpathogenic under customary test conditions—may have contributed to this neglect Today these obstacles no longer block the road the carrier state and silent infections negate as a fallacy the assumed corollary to the first postulate fulfillment of the third postulate has been accomplished often enough to establish the principle

Before presenting a few examples of endogenous infective diseases it may be useful to outline certain features common to the whole group It has been pointed out already that diseases associated with indigenous microorganisms cannot be sharply distinguished from exogenous infections in which latency or its equivalent is a conspicuous feature Indeed it may be noted that the very word endogenous is used only for convenience The group differs from endogenous reinfection in tuberculosis for example principally in that *M tuberculosis* is easily recognizable as a pathogen

The common features of endogenous infective diseases may be listed as follows (1) Microorganisms found in the indigenous biota are indispensable agents in the pathogenesis of endogenous infective diseases (2) The microbial agents of endogenous infective diseases occur in the indigenous biota in health but in disease they are either significantly increased in concentration in or near their usual sites or are found proliferating in an unusual site—in the tissues (3) The bacterial agents of endogenous infective diseases are characterized by low intrinsic pathogenicity (4) A state equivalent to latency in exogenous infections is characteristic of endogenous infective diseases which there

fore have no definable incubation period (5) *Endogenous bacterial diseases are not com*municable within the accepted limits of meaning of this term (6) Immunity, in the sense of specific protection against recurrence of a given endogenous infective disease is not recognized clinically rather the diseases have a marked tendency either to recur or to progress slowly over a period of many years (7) In endogenous infective diseases, causes or determinants other than the *activity of indigenous microbic agents are as* indispensable to pathogenesis as are the agents themselves Another feature of this group of diseases frequent but apparently not universal is that they are likely to be nonspecific with respect both to their microbic agents and to other determinants of *pathogenesis It is usually futile* to search for single causes of diseases in this group, or otherwise to attempt to deal with them by analogy with disease outside the group

SUBACUTE BACTERIAL ENDOCARDITIS

Subacute bacterial endocarditis (s b e) is a characteristic endogenous infection whose pathogenesis is rather well understood and comparatively simple Implantation on a previously damaged heart valve of nonhemolytic streptococci or other microorganisms follows an initial transitory bacteremia induced by surgical or comparable manipulation The organisms proliferate in and under cover of fibrin platelet thrombi which protect them from phagocytosis and other blood clearing mechanisms forming vegetations which lead to persistent bacteremia and in untreated cases to death by occlusion of the affected valve, other vascular accidents or serious embolism The microbic agents concerned are usually nonpathogens , pathogenesis seems to require of them only an ability to proliferate under conditions provided by the host

There seems to have been no marked reduction in the incidence of s b e since the advent of the antibiotic era (see e g Pankey, 1961), and although modern treatment has reduced mortality markedly—formerly it approximated 100 per cent—deaths continue to be common seldom fewer than 20 per cent of cases even in small favorable groups (e g Hamburger *et al*, 1961), and as high as 72 per cent in a group of older patients (Cummings *et al* 1960)

In s b e, indigenous viridans streptococci continue to be the most common organisms enterococci are also found in a significant minority of instances (see Toh and Ball 1960 Koenig and Kaye, 1961 Tompsett and Pizette 1962) Groupable streptococci other *than A D or N hemolytic or not have also* been found In addition many diverse indigenous species appear including uncommonly or rarely, such otherwise benign species as lactobacilli or veillonellae Mixed infections are found but not frequently A considerable proportion of cultures remain sterile perhaps in part because routine methods do not disclose them—as would be true of fastidiously anaerobic amphibionts (for recent reviews see Jackson and Allison 1961 Quinn and Colville 1961, Vogler *et al*, 1962a b)

Pre-existing cardiac damage most commonly affecting the mitral valve is an important antecedent of s b e In approximately 75 to 92 per cent of instances in which such damage is recognized it is rheumatic in origin in the remainder it may be arteriosclerotic congenital or syphilitic In many instances of rheumatic valvular injury the patient is unaware of the defect before the onset of s b e

The streptococci most frequently implicated in this disease and many of the other species recovered from blood cultures are nonpathogenic for laboratory animals by the usual routes of inoculation However progressive disease closely similar to s b e in man has been produced experimentally in animals by a variety of means including cardiac damage induced before intravenous inoculation of nonhemolytic streptococci Highman *et al* (1952) showed that cardiac damage could be induced in rats exposed intermittently for prolonged periods in a low pressure chamber to simulated altitudes of 25 000 feet Some of these animals developed spontaneous bacterial implants Repeated intravenous injection of *S mitis* or a single large dose of *S faecalis* yielded bac

terial endocarditis in a majority of the animals (See also Altland *et al* 1959 Walker and Hamburger 1959)

The bacteremia which leads to s b e is of diverse origin With indigenous microorganisms the mechanism may include trauma manipulation or massage of a mucous or skin surface Tonsillectomy and dental operations have been particularly incriminated especially in cases involving viridans streptococci However evidence for the association is often lacking It is recognized that manipulation of other loci with a normal flora (e g the genitourinary tract see Lein and Stander 1959 Koenig and Kaye 1961) may be responsible Dental interest in this problem is reflected in a considerable literature in which in addition to tooth extraction and other oral surgery (e g Schirger *et al* 1960) transient bacteremias have been induced especially by gingival and periodontal manipulation (Vargas *et al* 1959 Gutverg and Haberman 1962 Korn and Schaffer 1962) On the other hand cavity preparation pulpotomy (Beechen *et al* 1956) and root canal operations (Bender *et al* 1960) have been found not to induce bacteremia Bender and his co workers recommended that such treatment be chosen in preference to extraction in persons with valvular disease when this is feasible The occasional alternative suggestion that tooth extraction be performed prophylactically in susceptibles seems to be of doubtful validity Massaro and Katz (1960) recorded an instance in which viridans streptococcal s b e occurred in an edentulous man and mentioned 2 earlier cases

Specific therapy of s b e caused by penicillin sensitive streptococci (briefly reviewed by Hamburger *et al* 1961) continues to favor a combination of penicillin with streptomycin This combination also has a good record in enterococcal endocarditis even when in vitro sensitivity tests have not been favorable (Koenig and Kaye 1961 Tompsett and Pizette 1962) Control measures usually emphasize the administration of antibiotics before during and after surgery or other potentially precipitating manipulations in patients with known or suspected cardiac damage Several studies of this procedure agree that it reduces but does not abolish the incidence of bacteremia (e g Shirger *et al* 1960 Gutverg and Haberman 1962)

ACTINOMYCOSIS

A subacute or chronic usually progressive disease of orofacial thoracic or abdominal tissues actinomycosis produced by *A israelii* alone or perhaps in combination with other microorganisms is another clear example of endogenous infection In this instance however while host factors in pathogenesis seem to be essential to permit or enable the occasional invasion by a surface parasite the nature of these factors is poorly understood Actinomycosis occurs in man cattle and other animals It is characterized in man by the development of indurated granulating swellings chiefly in connective tissue by suppuration usually of limited extent and by the presence of *A israelii* in the pus or lesions The disease develops over periods ranging from a few weeks to a year or more and may spread widely by contiguity sometimes pointing toward the skin and forming fistulae that tend to heal and re form elsewhere rarely pointing toward mucous or serous membranes The organism may be disseminated through the blood or in the lungs through the bronchi The lymphatic system is only rarely involved Bone lesions are uncommon in man

Actinomycosis is generally thought to occur in the cervicofacial region somewhat more frequently than in all others combined Such cases are seen most frequently in dental or oral surgical clinics Fisher and Harvey (1956) found that of 90 cases treated over a 25 year period 55 per cent involved the abdominal wall or viscera 23 per cent were thoracic 13 per cent were cervicofacial and 9 per cent appeared in other areas The commonest *cervicofacial* lesions are seen on the cheek or submaxillary skin as indurated or edematous swellings often bluish or reddish in color with a tendency to form a series of irregular folds separated by furrows the healing area forming scars as new lesions develop *Thoracic* actinomycosis is found mainly in the lungs with the formation of abscesses and cavities which are usually small Extensive abscesses may be found in the bronchi and

their rupture may lead to dissemination of the infection by way of the bronchial tree Actinomycotic pleurisy and empyema have been observed as has involvement of the heart and the pericardium *Abdominal* actinomycosis may be found in any organ but is most common in the region of cecum and appendix From here the lesion may extend with suppurative foci and the formation of fibrous adhesions to the abdominal wall where skin lesions may appear similar to those of cervicofacial actinomycosis Or the lesion may remain circumscribed forming a fibromalike mass The liver is commonly attacked and lesions of the genital tract are relatively frequent The stomach the small intestine and the kidney are seldom affected Rarely actinomycosis may be found in the anorectal area or the testis

The microscopic appearance of the lesions of actinomycosis varies from that of an acute abscess with an abundance of polymorphonuclear cells to the more chronic lesion in which proliferating connective tissue is the most conspicuous feature Commonly the picture includes necrosis with an abundance of leukocytes surrounded in turn by granulation tissue and a profuse formation of dense fibrous tissue It is thus not characteristic unless *sulfur granules* are present These are frequently lacking in either tissue or pus and when present particularly in lesions in man may not show typical clubs Club bearing granules may be found in several distinct diseases distinguishable from those of true actinomycosis in gram stained but not in routine hematoxylin eosin sections Details of the typical granule are seen best under magnifications of 400 diameters or more It may be roughly circular or irregular in outline or may consist of several colonies of different size and shape that have coalesced The granule is composed of a dense reticulum of fibrils which stain violet by Gram s method but may otherwise stain irregularly Around the periphery the ends of individual filaments may project, with or without radially arranged hyaline clubs The clubs when present, take the eosin stain and are several times larger than the filaments whose ends they enclose Pine and Overman (1963) have found sulfur granules (of *A bovis* from cattle) to have essentially the same composition as organisms grown in vitro except that the sulfur granule contained about 50 per cent calcium phosphate

The epidemiology of actinomycosis is that of an endogenous infection as was clearly shown by Wolff and Israel in 1891 and by Wright in 1905 Nevertheless the pathogenesis of actinomycosis is incompletely known In the hands of earlier workers attempts to demonstrate pathogenicity of *A israelii* for common laboratory animals by the usual routes were usually unsuccessful or yielded only localized lesions

Repeated passage, trauma during inoculation or admixture with other bacteria were generally ineffectual However progressive and fatal experimental actinomycosis with typical granules and other pathologic signs has been produced—although again without regularity—by repeated inoculation at intervals that might have permitted development of allergy to the organism but allergy could not be demonstrated convincingly Meyer and Verges (1950) and Geister and Meyer (1951) have reported the consistent production of actinomycosis in mice by injecting pure cultures in association with gastric mucin Hazen *et al* (1952) produced typical actinomycosis in 21 of 28 young male hamsters with any of 8 strains of *A israelii* Gale and Waldron (1955) found that actinomycotic lesions with typical granules usually without clubs could be produced in mice with any of 7 strains of *A israelii* but the disease developed during the first week after inoculation and then tended to recede Guinea pigs inoculated with a single strain responded similarly These results may help to explain the failure of other workers who depended on gross illness or death as a sign of experimental infection Strains of *A israelii* isolated from mucous membranes have been found as capable of inducing lesions as strains obtained from the natural disease The experimental findings as a whole leave the pathogenesis of the progressive disease in man uncertain The comparative rarity of actinomycosis suggests that autoinoculation resulting from minor trauma perhaps even when repeated can be no more than a contributory incident More severe traumatic events have often been associated with actinomycosis e g a tooth extraction or other

injury to mouth or throat human bite or knuckle injuries from a blow to the teeth or aspiration of an extracted tooth or tooth fragment into the lungs *A israelii* has been found in salivary calculus and detached masses of tartar may be involved in comparable traumatic accidents Actinomycotic pus from closed lesions frequently perhaps invariably contains other organisms in addition to *A israelii* the suggestion has been made that a mixed infection may be important in establishing the disease

Although the finding of microscopically typical sulfur granules is presumptively diagnostic of actinomycosis in man the diagnosis cannot be considered as established unless *A israelii* is isolated from the lesions For this purpose plates should be serially streaked on brain heart medium containing 2 per cent agar or on blood agar and incubated anaerobically with 5 per cent CO for 4 to 6 days at 37 The opaque white heaped up colonies of *A israelii* particularly the rough colonies can be identified easily even in the presence of abundant contaminating growth but smooth colonies may be indistinguishable from those of diphtheroids Isolation may be made into tubes containing a 10 cm column of glucose infusion broth in which the organism typically grows after aerobic incubation as a crumblike or tiny cauliflowerlike mass in the bottom with the supernatant broth clear but smooth strains may grow more diffusely In glucose agar shake cultures incubated aerobically for 4 to 6 days the typical picture is that of whitish spherical or mulberry shaped colonies of varying size up to 3 mm in diameter growing only in the depths of the agar often with a dense zone of colonies 0 5 to 2 cm below the free surface Recovery of an occasional *A israelii* colony from materials subjected to direct contamination from a mucous membrane (e g in expectorated sputum) has no diagnostic significance

A israelii is sensitive to several antibiotics in vitro (see McVay and Sprunt 1953) Penicillin tetracyclines chloramphenicol and isoniazid have all been reported as effective with occasional failures High dosage for sustained periods is usually used accompanied by surgical measures where possible (See also Peabody and Seabury 1960)

BACTEROIDES AND ANAEROBIC STREPTOCOCCI—MIXED OR SYNERGISTIC ANAEROBIC INFECTIVE DISEASES

A diverse group of diseases of animals and man has been associated for many years with bacteroides or anaerobic streptococci separately or together or mixed with other bacterial species Bacteroides were described in calf diphtheria in 1884 by Loeffler and were found in and cultivated from necrotic disease of other animals in the years immediately following (see Lahelle 1947 Rosebury 1962) Bacteroides were recovered from fetid and gangrenous suppurations in man by Veillon and Zuber in 1897 Veillon also isolated anaerobic streptococci from the lesions of Ludwig s angina perinephric abscess and bartholinitis in 1893 Schottmuller first cultivated anaerobic streptococci from the blood in 1910 These species perhaps occasionally alone more often in bacterial associations are capable of inducing significant disease However the pathogenesis is virtually unknown The clinical processes concerned may be classified in three groups In the first anaerobic or micro aerophilic streptococci occur with other indigenous bacteria in a spreading gangrene of the skin or in wound infections In the second either anaerobic streptococci or bacteroides or both recovered in blood cultures with or without additional species are found in diseases beginning especially in the pharyngeal intestinal or genital mucous membranes and progressing to a septicemia or pyemia often associated with thrombophlebitis In the third group in which indigenous spirochetes are prominently associated with bacteroides anaerobic streptococci and a profusion of other indigenous species—the so called fusospirochetal diseases—the lesions are usually inflammatory or destructive processes of the mucous membranes themselves or of directly adjacent tissues The last group is considered separately in the following section the first two are dealt with here as a unit The distinction between the three groups is not sharp It need hardly be emphasized that collectively these diseases occupy a distinctly higher level of complexity than the endogenous infective diseases considered previously and it is not

their rupture may lead to dissemination of the infection by way of the bronchial tree Actinomycotic pleurisy and empyema have been observed as has involvement of the heart and the pericardium *Abdominal* actinomycosis may be found in any organ but is most common in the region of cecum and appendix From here the lesion may extend with suppurative foci and the formation of fibrous adhesions to the abdominal wall where skin lesions may appear similar to those of cervicofacial actinomycosis Or the lesion may remain circumscribed forming a fibromalike mass The liver is commonly attacked and lesions of the genital tract are relatively frequent The stomach the small intestine and the kidney are seldom affected Rarely actinomycosis may be found in the anorectal area or the testis

The microscopic appearance of the lesions of actinomycosis varies from that of an acute abscess with an abundance of polymorphonuclear cells to the more chronic lesion in which proliferating connective tissue is the most conspicuous feature Commonly the picture includes necrosis with an abundance of leukocytes surrounded in turn by granulation tissue and a profuse formation of dense fibrous tissue It is thus not characteristic unless *sulfur granules* are present These are frequently lacking in either tissue or pus and when present particularly in lesions in man may not show typical clubs Club bearing granules may be found in several distinct diseases distinguishable from those of true actinomycosis in gram stained but not in routine hematoxylin-eosin sections Details of the typical granule are seen best under magnifications of 400 diameters or more It may be roughly circular or irregular in outline or may consist of several colonies of different size and shape that have coalesced The granule is composed of a dense reticulum of fibrils which stain violet by Gram s method but may otherwise stain irregularly Around the periphery the ends of individual filaments may project with or without radially arranged hyaline clubs The clubs when present take the eosin stain and are several times larger than the filaments whose ends they enclose Pine and Overman (1963) have found sulfur granules (of *A bovis* from cattle) to have essentially the same composition as organisms grown in vitro except that the sulfur granule contained about 50 per cent calcium phosphate

The epidemiology of actinomycosis is that of an endogenous infection as was clearly shown by Wolff and Israel in 1891 and by Wright in 1905 Nevertheless the pathogenesis of actinomycosis is incompletely known In the hands of earlier workers attempts to demonstrate pathogenicity of *A israelii* for common laboratory animals by the usual routes were usually unsuccessful or yielded only localized lesions

Repeated passage trauma during inoculation or admixture with other bacteria were generally ineffectual However, progressive and fatal experimental actinomycosis with typical granules and other pathologic signs has been produced—although again without regularity—by repeated inoculation at intervals that might have permitted development of allergy to the organism but allergy could not be demonstrated convincingly Meyer and Verges (1950) and Geister and Meyer (1951) have reported the consistent production of actinomycosis in mice by injecting pure cultures in association with gastric mucin Hazen *et al* (1952) produced typical actinomycosis in 21 of 28 young male hamsters with any of 8 strains of *A israelii* Gale and Waldron (1955) found that actinomycotic lesions with typical granules, usually without clubs could be produced in mice with any of 7 strains of *A israelii* but the disease developed during the first week after inoculation and then tended to recede Guinea pigs inoculated with a single strain responded similarly These results may help to explain the failure of other workers who depended on gross illness or death as a sign of experimental infection Strains of *A israelii* isolated from mucous membranes have been found as capable of inducing lesions as strains obtained from the natural disease The experimental findings as a whole leave the pathogenesis of the progressive disease in man uncertain The comparative rarity of actinomycosis suggests that autoinoculation resulting from minor trauma perhaps even when repeated can be no more than a contributory incident More severe traumatic events have often been associated with actinomycosis e g a tooth extraction or other

extracts of the latter species prepared by grinding with sand digestion with trypsin or extraction with trichloracetic acid had little or no effect

In vitro antibiotic sensitivity tests with these organisms have been reported most recently by Garrod (1955) and by Lodenkamper and Stienen (1955) The former found *B nigrescens B funduliformis* and a fusiform bacillus to be most sensitive to penicillin but *B fragilis* was penicillin resistant All 4 species were also sensitive to oxytetracycline and chloramphenicol more so to the former erythromycin was effective against *B nigrescens* and polymyxin against the fusiform bacillus and *B funduliformis* Streptomycin and bacitracin were generally ineffective The German workers studied both bacteroides and anaerobic cocci separately and as mixtures Best results were obtained with the tetracyclines but resistant strains were found to nearly all antibiotics tested

Such clinical data as are available are generally consistent with these findings Tetracyclines and chloramphenicol have been used effectively penicillin streptomycin and sulfonamides have usually failed See McHenry *et al* (1961) Tynes and Frommeyer (1962)

FUSOSPIROCHETAL DISEASES

The group of diseases in which indigenous spirochetes appear as prominent components of a profuse mixed biota include some of the most widespread ills of mankind The early literature on fusospirochetal disease has been reviewed by Rosebury (1938) The group includes the periodontal diseases which are treated in the next section the complex of ulceromembranous stomatitis or pharyngitis or equivalent disease of the external genitalia and the extreme form of this process noma comparable putrid necrotic diseases of the respiratory and the intestinal tracts a form of tropical ulcer of the skin and similar lesions of other areas Fusospirochetal disease seems always to be superimposed on tissue damage induced by other agencies including scurvy pellagra inanition or other nutritional disturbances agranulocytosis or radiation injury viral infections including measles and primary herpes simplex and probably more commonly complexes or constellations of factors exemplified in the periodontal disease group

Experimental fusospirochetal disease was produced first in rabbits by Veszpremi in 1905 and 1907 and since repeatedly in guinea pigs and other animals by many workers The lesions have been initiated with whole exudates from any of a series of fusospirochetal diseases in man and are regularly transmissible with the resulting animal lesion exudates inoculated by any of several routes Subcutaneous inoculation of guinea pigs the method most commonly used yields either large necrotic abscesses tending to evacuate and heal or a spreading cellulitis which either heals after belated localization or more typically leads to death in 2 to 7 days In the more severe infections the exudate is serofibrinous it is always foul and contains spirochetes in a complex mixture of other bacteria In animals sacrificed while moribund a cellulitis is found dissecting the fascial planes from the point of inoculation the viscera are somewhat congested and the adrenals are enlarged and hemorrhagic but no visceral infection is found In such animals as in comparable disease in man spirochetes have been found in vital tissue while other bacteria are limited sometimes sharply to the distal border of the necrotic zone Pathologic changes are those of acute inflammation in fatal infection the cellular response is disorderly or at times apparently entirely lacking The species in one guinea pig passage exudate (Rosebury *et al* 1950) in which the LD_{50} was estimated as 8×10^9 organisms were identified as spirochetes of the *T dentium* variety *Fusobacterium fusiforme* and atypical fusiform bacilli both *Vibrio sputorum* and *Spirillum sputigenum* unidentified bacteroides *Str mitis* and incompletely characterized anaerobic streptococci and a miscellany of gram positive bacilli all except *Str mitis* appeared to be strict anaerobes From another passage exudate Macdonald *et al* (1954) isolated a similar range of species but only atypical fusiform organisms were present as was an unidentified motile gram negative anaerobic bacillus and *B nigrescens S sputigenum* was not found A later study by these workers (Macdonald *et al* 1956) indicates that one of the cultures was an aerobic diphtheroid

surprising that the role of indigenous micro organisms in these processes is frequently dis regarded or overlooked The record suggests that these organisms have been found among hospital cases whenever appropriate means have been employed to detect them (See Tynes and Utz 1960 McHenry *et al*, 1961 Johnson 1962, Tynes and Frommeyer 1963 and Murphy *et al* 1963)

The role of anaerobic streptococci and bacteroides in endogenous infective diseases is made clear most convincingly by studies of their experimental pathogenicity and is supported by the results of antibiotic therapy in man The following discussion is limited to these two topics For reviews of other aspects of this subject see Lahelle (1947) Carter *et al* (1953) and Alston (1955)

In pure culture anaerobic streptococci have been found to be nonpathogenic for animals almost uniformly As for bacteroides, on the other hand early workers had little difficulty demonstrating pathogenicity especially with strains isolated from animal disease, but since about 1935 such tests have nearly always resulted negatively Dack (1940) suggested that animals used by the earlier workers may have been fed deficient diets The more significant findings relating to pathogenicity are to be found in studies with mixtures of pure cultures which have yielded positive results consistently when the mixtures contained organisms identified as or resembling *P evolutus* *P putridus* (or incompletely identified anaerobic cocci) *B funduliformis* *B fragilis* or *B nigrescens* Meleney (1931), Henthorne and McDonald (1936) and Steinhorn (1945) have reported that mixtures of anaerobic streptococci with staphylococci or unnamed second species inoculated subcutaneously produced ulcerative, necrotic or gangrenous lesions, often very destructive and sometimes fatal in guinea pigs, mice or other animals, the individual cultures inoculated alone showed little or no pathogenicity Altemeier (1942) produced severe cellulitis with abscess formation ulceration or gangrene in guinea pigs with mixtures containing 4 to 6 pure cultures isolated from peritonitis in man The pure cultures by themselves were again noninfective for the most part Five of the 6 mixtures included either an anaerobic streptococcus or a bacteroides culture, the other species studied included aerobic cocci coliforms *C hofmannii* and *Ps aeruginosa* Ryff and Lee (1946) found that a strain of *B funduliformis* isolated from necrotic stomatitis in a calf produced lesions independently when inoculated in 0 5 ml amounts into the labial skin of rabbits When 0 1 ml of this culture in itself innocuous was mixed with an equal volume of one of a long series of pure cultures of other species most of which were also nonpathogenic independently necrotic or suppurative lesions resulted in the majority of trials Among the ancillary non pathogens were indigenous aerobic streptococci, micrococci or corynebacteria *B subtilis* and *L bifidus* In additional experiments by these workers more severe lesions resulted in rabbits fed deficient diets and then inoculated similarly with the bacteroides cultures mixed with an aerobic streptococcus or *B subtilis* The most extensive studies of this kind were reported by Hite *et al* in 1949 These workers used a group of cultures isolated from the female genital tract under either normal or pathologic conditions including *B funduliformis* *B nigrescens* and other bacteroides, a strain listed as *Bact fusiformis* but not otherwise identified a group of anaerobic streptococci and other cocci not clearly characterized and the aerobes *Str liquefaciens* *Str mitis* and *Staph albus* Subcutaneous inoculation of mice with single pure cultures of the anaerobes again yielded minimal lesions or none the aerobes alone were nonpathogenic In pairs however, comprising either two anaerobes or anaerobe plus aerobe inoculation of half volumes of each yielded lesions with many of the mixtures described as necrotizing often suppurative sometimes extending to the peritoneum and the viscera and in some instances leading to death of the animal The most significantly pathogenic mixtures contained anaerobic cocci with either *Str liquefaciens* or the fusiform bacillus bacteroides with any of the aerobes or, curiously *B funduliformis* with either *B nigrescens* or the fusiform bacillus It is of interest that mixtures of bacteroides with the anaerobic cocci were generally ineffectual Synergistic infection was also observed when *Str liquefaciens* was mixed with heat killed *B funduliformis* but mixtures of the same streptococcus with

cal massive overgrowth of the fusospirochetal biota is present in all three varieties and is indistinguishable among them The inflammatory and destructive symptoms of periodontal disease are referable to fusospirochetal infection which in turn may be traced to tissue damage associated with gingival accumulations of food desquamated epithelium and salivary calculus the first two serving as pabulum for the biota the last presumably as an additional source of irritation and tissue deformation These antecedents of infection may in turn be attributed to a wide range of subtle local or general disturbances in the structural and functional relationships of the dental periodontal apparatus

The pattern of ideal relationships entails a complex equilibrium changing with time between functional stress upon the teeth occlusal tooth wear and continued eruption of the teeth and apposition of cementum probably accompanied by a rootward shift of the terminal epithelium of the gingiva Functional stress transmitted through the teeth maintains the integrity of the periodontal ligament and the alveolar bone and both structures shift and change with age to compensate for cusp loss and interproximal attrition Additional compensatory changes with age involve these tissues the dental arches as units and the temporomandibular joints Disturbances in this process which alter the ideal relationships of the attached epithelium the gingival margin and the underlying bony support impair the hygienic mechanism whereby ideally functional movements prevent gingival accumulations of gross bacterial pabulum such accumulations and the consequent infection aggravate the cycle of changes

The circumstances that induce periodontal disharmony are themselves varied and complex They may include any agency that leads to impaired cell metabolism of the tissues concerned nutritional or hormonal upsets intoxications or exogenous infections abetted by tooth loss or damage resulting from dental caries or by faulty dental restorations and doubtless also by the character of ingested food as it promotes or fails to promote healthy function and retention of food residues in addition to its nutritional quality Emotional disturbances interrelated with metabolic upsets and with salivary function stimulated by gross fusospirochetal infection clenching and grinding of the teeth neglect of nutrition and toothbrushing must also be included among the forces leading to periodontal disease It is probable that the customary diet of the present day promotes a marginal gingivitis if it is inadequately compensated for by toothbrushing this form of the disease usually responds quickly to simple hygienic treatment If treatment is deferred the cycle of changes proceeds to suppurative periodontal breakdown which can usually be arrested by similar treatment of the more deeply involved tissues Under more acute stress such as fatigue intoxication and deficiency especially of B group vitamins the ulcerative form of gingivitis may appear Outbreaks of this condition have occurred under group conditions especially in wartime It is also likely that a metabolic disturbance such as a transient deficiency of ascorbic acid may initiate a cycle of changes in the periodontal tissues that eventuate in breakdown many years later Ascorbic acid deficiency and consequent failure of collagen formation lead to a condition in guinea pigs that resembles acute periodontal breakdown Such metabolic disturbances are particularly implicated in a form of periodontal pocket formation that is not accompanied by gingivitis

Periodontal disease has been observed or produced experimentally in several animal species (see Gupta and Shaw 1956 Baer and White 1960 Macdonald *et al* 1960) but findings thus far have shed little light on the problem in man Alveolar bone loss one of the features of chronic periodontal disease in man has been found in germ free mice by Baer and Newton (1959) Treatment of periodontal disease varies with the clinical entity Chemotherapy is indicated only to relieve acute symptoms e g in ulcerative gingivitis recurrence is likely unless other measures are employed Such measures emphasize the removal of gingival and subgingival microbial pabulum and tartar and where necessary the correction of faulty dental restorations and of defects of occlusion and alignment of the teeth Local treatment of this kind supplemented by toothbrushing is frequently sufficient in itself to arrest the dis

Socransky *et al* (1963) and Gibbons *et al* (1963) have reported quantitative studies of the gingival microbiota in which the micro organisms were similar in health and in peri odontal disease except for a significant in crease in spirochetes in the latter there was more than a 10 fold increase of the total flora in disease

Attempts to reproduce transmissible fuso spirochetal infections with recombined mix tures of pure cultures and thus to define the essential component species have yielded equivocal results up to the present The earlier studies initiated by Kritchewski and Seguin in 1920 have been reviewed by Rose bury *et al* (1950) D T Smith in 1932 and Proske and Sayers in 1934 reported that a mixture of pure cultures of 4 anaerobes —*T microdentium* a fusiform bacillus a vibrio and a streptococcus—was the only effective combination among many tested Rosebury *et al* (1950) using the cultures previously noted and others were unable to produce typical or transmissible fusospiro chetal infection with similar or other com binations However typical infection could be induced by inoculation of cultures grown from whole exudate as a mixture through 10 successive culture passages without loss of infectivity hence the infective mixture is cultivable in vitro as such An estimate of the dilution of the original inoculum entailed by this procedure was in line with other studies which suggested that a virus is not a com ponent of the infective complex Successful recombination was accomplished by Mac donald *et al* (1954) who produced typical transmissible fusospirochetal infection with material taken from the hub of wheel plates' on which 16 cultures isolated from guinea pig exudate had been streaked radially to a common center spirochetes from a cul ture having been added at the hub In 3 of 9 trials in which the spirochetes and all or all but one of the spoke cultures grew under these conditions an emulsion of the mixture reproduced the typical disease In a subse quent study Macdonald *et al* (1956) using the wheel plate method recombined the same 16 cultures in various groups and concluded that the minimum group capable of eliciting typical transmissible infection consisted of 2 strains of *Bacteroides* (including *B nigrescens*), an unidentified motile gram negative anaerobic bacillus and an aerobic diphther oid The diphtheroid was thought to serve the nonspecific function of supporting growth of *B nigrescens* None of the species con sidered essential by D T Smith and Proske and Sayers was present in the inoculum nor did any appear in the exudates from which the 4 species employed were reisolated The positive aspects of these findings are in line with those noted previously in experimental studies of bacteroides but their negative as pects as Macdonald and his co workers themselves suggested and as Berger (1957) has pointed out cannot be considered as demonstrating that neither spirochetes nor typical fusiform bacilli participate in fuso spirochetal infections

The probability that bacteroides and fuso spirochetal diseases although pathologically similar may be etiologically distinct is sup- ported by findings with penicillin therapy It has been noted that *B fragilis* is resistant to penicillin in vitro and that although other bacteroides are penicillin sensitive clinical trials with this antibiotic have yielded poor results The value of penicillin in controlling the infective phase of fusospirochetal disease in man on the other hand was established early and has included a wide range of fuso spirochetal diseases among them the highly destructive and fatal forms in agranulocytosis (Robertson 1949) and noma (Jelliffe 1953)

PERIODONTAL DISEASE

The following brief treatment of periodon tal disease is included here for its intrinsic interest and as an example of the presumed interplay of host factors in an endogenous infective disease The three principal varie ties of periodontal disease comprise a sub acute or chronic inflammation of the gingival margin (marginal gingivitis) an acute ulcer ative variety (Vincent s gingivitis) and perio- dontal breakdown (pyorrhea) the most chronic form characterized by progressive development of pockets opening at the inner gingival margin Chronic periodontal disease occurs nearly universally in the 4th or the 5th decade of life and is mainly re sponsible for tooth loss among adults A typi

cal massive overgrowth of the fusospirochetal biota is present in all three varieties and is indistinguishable among them The inflammatory and destructive symptoms of periodontal disease are referable to fusospirochetal infection which in turn may be traced to tissue damage associated with gingival accumulations of food desquamated epithelium and salivary calculus the first two serving as pabulum for the biota the last presumably as an additional source of irritation and tissue deformation These antecedents of infection may in turn be attributed to a wide range of subtle local or general disturbances in the structural and functional relationships of the dental periodontal apparatus

The pattern of ideal relationships entails a complex equilibrium changing with time between functional stress upon the teeth occlusal tooth wear and continued eruption of the teeth and apposition of cementum probably accompanied by a rootward shift of the terminal epithelium of the gingiva Functional stress transmitted through the teeth maintains the integrity of the periodontal ligament and the alveolar bone and both structures shift and change with age to compensate for cusp loss and interproximal attrition Additional compensatory changes with age involve these tissues the dental arches as units and the temporomandibular joints Disturbances in this process which alter the ideal relationships of the attached epithelium the gingival margin and the underlying bony support impair the hygienic mechanism whereby ideally functional movements prevent gingival accumulations of gross bacterial pabulum such accumulations and the consequent infection aggravate the cycle of changes

The circumstances that induce periodontal disharmony are themselves varied and complex They may include any agency that leads to impaired cell metabolism of the tissues concerned nutritional or hormonal upsets intoxications or exogenous infections abetted by tooth loss or damage resulting from dental caries or by faulty dental restorations and doubtless also by the character of ingested food as it promotes or fails to promote healthy function and retention of food residues in addition to its nutritional quality Emotional disturbances interrelated with metabolic upsets and with salivary function stimulated by gross fusospirochetal infection clenching and grinding of the teeth neglect of nutrition and toothbrushing must also be included among the forces leading to periodontal disease It is probable that the customary diet of the present day promotes a marginal gingivitis if it is inadequately compensated for by toothbrushing this form of the disease usually responds quickly to simple hygienic treatment If treatment is deferred the cycle of changes proceeds to suppurative periodontal breakdown which can usually be arrested by similar treatment of the more deeply involved tissues Under more acute stress such as fatigue intoxication and deficiency especially of B group vitamins the ulcerative form of gingivitis may appear Outbreaks of this condition have occurred under group conditions especially in wartime It is also likely that a metabolic disturbance such as a transient deficiency of ascorbic acid may initiate a cycle of changes in the periodontal tissues that eventuate in breakdown many years later Ascorbic acid deficiency and consequent failure of collagen formation lead to a condition in guinea pigs that resembles acute periodontal breakdown Such metabolic disturbances are particularly implicated in a form of periodontal pocket formation that is not accompanied by gingivitis

Periodontal disease has been observed or produced experimentally in several animal species (see Gupta and Shaw 1956 Baer and White 1960 Macdonald *et al* 1960) but findings thus far have shed little light on the problem in man Alveolar bone loss one of the features of chronic periodontal disease in man has been found in germ free mice by Baer and Newton (1959) Treatment of periodontal disease varies with the clinical entity Chemotherapy is indicated only to relieve acute symptoms e g in ulcerative gingivitis recurrence is likely unless other measures are employed Such measures emphasize the removal of gingival and subgingival microbial pabulum and tartar and where necessary the correction of faulty dental restorations and of defects of occlusion and alignment of the teeth Local treatment of this kind supplemented by toothbrushing is frequently sufficient in itself to arrest the dis

ease Surgical procedures for elimination of pockets and diseased gingival tissue are widely and successfully used For additional details and references see Rosebury 1952 *1955 Glickman 1956 1963*

DENTAL CARIES

Dental caries one of the most prevalent of all diseases is a distinctive process of disintegration of the hard dental tissues proceeding centripetally from the exposed surface Its unique characteristics are determined in part by the tissues in which it appears which are either entirely noncellular (enamel) or contain only the processes of pulpal cells (dentin) and hence do not react to injury as do cellular tissues Most carious lesions begin at one of three sites in the pits and fissures of the functional surfaces at approximating areas of contact and on surfaces of enamel or exposed cementum or dentin near the gingival margin Lesions in the first two areas are most common in the period immediately following tooth eruption, i e, in childhood and adolescence There is nearly universal agreement on the main lines of pathogenesis stemming principally from the studies of W D Miller in 1890 Research during the last decade has generally supported this approach while elucidating many details (e g biochemical and histochemical studies Mandel, 1955 Opdyke 1962 Zipkin and Gold 1963 microradiography Bergman and Engfeldt 1954 Guzman *et al* 1957 electron microscopy Scott and Albright 1954 Helmcke 1959 and in vitro experimental caries Forziati *et al* 1956 Rowles *et al* 1963)

According to this view caries is initiated by acid products of bacterial fermentation of carbohydrates formed locally at sites of food accumulation or impaction Demineralization of enamel (or of dentin or cementum if the lesion begins in these tissues) appears to be the first step in the process subsequent steps may vary in seqeunce depending in part on the site and on the rate of progress of the lesion They include bacterial invasion proteolysis of enamel matrix, decalcification followed by digestion of dentin or cementum and loss of tissue by minute or gross fracture consequent on both function and forces associated with demineralization such as shrinkage and gas formation The bacterial species involved are almost certainly mixed in all instances but lactobacilli probably play a distinctive role in the mixture they alone among bacterial species recovered from caries have been found to be significantly increased in relation to clinical caries activity and their ability both to produce and to withstand low pH levels is unlikely to be coincidental The failure of germ free rats given sterilized caries producing diets to develop lesions (Orland 1954) confirmed the indispensability of microorganisms in the process Keyes (1960) has reported that experimental caries in hamsters and rats is infectious and transmissible under laboratory conditions but applicability of these findings to man is doubtful Whether the finding that rodent caries can be initiated specifically by certain streptococci (Fitzgerald and Keyes 1960 Keyes and Fitzgerald 1962) can be applied to man is also conjectural (Fitzgerald 1963)

For the most part our knowledge of the pathogenesis of caries is consistent with the fact that the disease is nearly universal in modern man Its apparently essential ingredients—retentive sites on the teeth the participating microorganisms and the required pabulum as well as the susceptibility of the teeth to disintegration all appear to be nearly ubiquitous Yet the occasional complete absence of caries in an adult may be attributable in part to the first factor, tooth form and dental architecture presumably implying a genetic component and the most probable mechanism for the protective effect of fluoride ion seems to be related to the last item the acid solubility of the dental tissues Nevertheless wide individual variation both in prevalence and in rate of progress of caries examined in detailed context points to the operation of additional factors and provides at least potentially means toward control

Experimental caries in hamsters and certain experimental lesions in rats seem to be most comparable with dental caries in man From the studies of Rosebury *et al* (see Rosebury 1938b) Sognnaes (1948) and Gustafson *et al* (1953 1955) emerge a group of interdependent determinants of caries susceptibility that seem to be consistent

with the human disease These include (1) the retentiveness of carbohydrate foods as determined by their physical state (2) the metabolic availability of the carbohydrate as substrate for fermentation (3) dental function or lack of function as it promotes or prevents food retention (4) a protective role of dietary fat perhaps acting by retarding carbohydrate solubility and (5) many other conditions less clearly defined including nutritional endocrine and other factors affecting the structure of the dental tissues salivary flow and composition and the pabulum retaining propensities of periodontal (interproximal and gingival) areas There is cogent evidence that starchy foods in dry compact form (e g raw rice or corn in animals hard fat free biscuit in both man and rats) serve as the initiating substrate for caries by forcible impaction into retentive sites On the other hand certain sugars especially sucrose and fructose but not starch or dextrin incorporated in the diet in dry finely divided form promote caries particularly in hamsters in proportion to their concentration In this instance it appears that impaired function evidenced after extraction of opposing teeth is necessary to permit accumulation or prevent removal of the pabulum When to such sugar diets enough distilled water was added to dissolve the carbohydrate caries in hamsters was markedly reduced suggesting that the major cariogenic effect of the diet is exerted in the mouth and not via nutritional channels (Gustafson *et al* 1955) Retardation of caries by inclusion of fat in the diet first noted in studies with children by Mellanby *et al* (see Committee 1936) has been observed in rats by Rosebury and Karshan (1935 1939) and Granados *et al* (1948) and in hamsters by Gustafson *et al* (1955) These findings suggest the possibility of preparing noncariogenic carbohydrate foods perhaps even confections by appropriate admixture with fats Among other influences on caries it may be noted that abundant evidence from studies both in man and in experimental animals indicates that if basic cariogenic conditions are present nutritional adequacy e g of vitamin D decreases or retards the progress of the lesions

Diagnosis of dental caries is made clinically with the aid of roentgenograms Counts of lactobacilli in saliva and other caries activity tests are useful principally in confirming a clinical diagnosis of rampant caries and as a sensitive index in the individual patient of the progress of attempts at dietary control Control of unusually high caries activity in children has been effective by drastic limitation of carbohydrate intake The use of a variety of dentifrices containing alleged anticariogenic agents is of doubtful utility but carefully supervised toothbrushing with any dentifrice or none may have some value Caries can be arrested by the traditional dental practice of removing involved tissue and replacing it with inert filling materials The fluoridation of public water supplies to the average level of 1 part per million has been fully established as nontoxic and effective in reducing the community prevalence of caries by 60 per cent or more most actively in children born and reared on fluoridated water but with distinct value when started at any age (see Arnold 1957 Hayes Littleton and White 1957) This now widespread practice is probably the most thoroughly studied of all public health procedures its effectiveness is beyond serious question but it is capable of solving only approximately half the problem of dental caries The effectiveness of topical application of 2 per cent NaF to the teeth of children has also been clearly demonstrated and is applicable where community fluoridation is not feasible The mechanism of inhibition of caries by fluoride seems to involve its incorporation in enamel as fluorapatite

The Hemolytic Streptococci

The streptococci comprise a large and biologically diverse group of microorganisms. The principal criteria for classifying them are morphologic. In general, streptococci can be defined as gram-positive organisms, spherical or oval in shape, that tend to grow in chains. With the exception of the pneumococci, which are usually considered separately by medical bacteriologists because of their unique biologic characteristics, those streptococci which possess primary pathogenicity for man and animals belong to the subdivision of hemolytic streptococci. The nonhemolytic streptococci are saprophytic, and many species can be found among the flora of the upper respiratory and the intestinal tracts of normal individuals. They are sometimes found in association with infectious processes, most commonly when some predisposing structural abnormality is present, as in bacterial endocarditis, urinary tract infections, or secondary wound infections.

Hemolytic streptococci cause the lysis of mammalian red blood cells, a property which is useful in the initial isolation and identification of these organisms in culture material. As a result of extensive serologic studies they have been divided into a number of distinct serologic groups which are related in some degree to the natural habitat and the pathogenicity of the organism. Accordingly, serologic group has assumed primary importance in the identification of pathogenic streptococci. It has become apparent that hemolytic streptococci of a single group, group A, are not only responsible for most of the acute streptococcal disease of man but also are involved in the initiation of late sequelae such as rheumatic fever and glomerulonephritis.

HISTORY

Streptococci were first seen in materials obtained from certain human infections. Thus Billroth (1874) described globular chains of microorganisms in erysipelas and wound infections, and Pasteur (1879) demonstrated similar organisms in the blood of a patient with puerperal sepsis. Ogston (1881) isolated cocci growing in chains from acute abscesses and used animal experiments to demonstrate the pathogenicity of the organisms after they had been grown on artificial media. Following the demonstration by Koch (1881) that streptococci were present with great regularity in excised erysipelas lesions, Fehleisen (1882, 1883) grew the organism in pure culture from such areas and induced typical erysipelas in human beings with subcultures.

Organisms with similar characteristics were subsequently obtained from a wide variety of materials, and considerable difficulty arose concerning their identification and classification. Inevitably, many streptococci were considered to be specific for the disease entity in which they appeared, and as a result such names as *Streptococcus erysipelatis* and *Streptococcus scarlatinae* came into use. Attempts to arrive at a system of classification

by studying biochemical and physiologic properties such as the pattern of fermentation by various carbohydrates did not prove to be of great value since no clear relationship between these findings and disease producing capacity could be established The differentiation of streptococci into hemolytic green and indifferent strains based on their action on red blood cells in vitro was first proposed by Schottmuller (1903) In his elaboration of this technic Brown (1919) introduced the terms alpha beta and gamma to describe slight hemolysis with greening frank hemolysis or no effect on erythrocytes respectively It was recognized early that pathogenic streptococci for the most part fell in the truly hemolytic (beta) category

A useful system for the classification of hemolytic streptococci was gradually evolved by the application of serologic technics Although not historically the first step a development of primary importance in bringing order into the study of streptococci came with the separation of these organisms into well defined serologic groups by Lancefield (1933) It was clear that most strains associated with human infections belonged to a single serologic group designated group A The occurrence of serologically differentiable types among human strains had been demonstrated earlier by agglutination and mouse protection tests (Dochez Avery and Lancefield 1919) The further development of type differentiation of human strains was pursued by different approaches in 2 laboratories Lancefield (1928a) devised a precipitin technic for typing based on the use of extracts containing type specific protein antigens and Griffith (1927 1934) classified streptococcal strains by applying a slide agglutination technic Information obtained from the grouping and the typing of hemolytic streptococci established the fact that the use of disease specific names is not justified since group A strains of a single type can be recovered from a variety of disease entities More important the serologic classification of streptococci supplied the tools required for a detailed study of the bacteriology the immunology and the epidemiology of streptococcal disease

MORPHOLOGY

The outstanding morphologic characteristic of streptococci is their tendency to grow in chains At certain stages of the growth cycle the individual cocci are spheroid However during growth of the organisms prior to division they become elongated on an axis parallel with that of the chain and assume an ovoid appearance The average diameter of the cocci is approximately 1 micron although there is considerable variation in size and certain minute streptococci may be one fourth to one half this size When growing under unfavorable conditions bizarre forms frequently appear with irregularities in the size the shape and the gram positivity of cocci even within a single chain In young actively growing cultures in favorable media such as serum or blood broth the cocci are uniform and the chains appear in their most characteristic form

After elongation during growth the cocci divide in a plane perpendicular to the long axis of the chain Because the individual cocci divide into pairs a diplococcoid appearance of the members of a chain is often quite striking Chaining results from the fact that a connecting link between the cocci probably composed of material like that forming the cell wall is retained following division These intercellular bridges are not easily broken and withstand such procedures as shaking however the chains can be disrupted without extensive destruction of cocci by subjecting them to brief periods of sonic oscillation (Slade and Slamp 1956) The length of the chains varies within wide limits and is influenced to some degree by the nature of the culture medium Many hemolytic streptococci grow in relatively short chains of 8 to 10 members others much longer Occasionally one will find extremely long chains suggesting that each individual chain of the inoculum has continued to increase in length without disrupting during growth This type of chain formation is more common among certain of the nonhemolytic streptococci

The chain forming property has an important bearing on the interpretation of quantitative studies on the growth of streptococci The usual technic for determining the number of viable bacterial cells depends on count

composition are formed by certain members of group C These capsules are composed largely of hyaluronic acid which is either identical with or very closely related to the hyaluronic acid found in mammalian tissues Capsules are most readily demonstrated microscopically in very young actively growing cultures in enriched media With continued growth the hyaluronic acid is released into solution in the medium and capsules are no longer demonstrable The capsules are seen most easily in wet preparations prepared by the India ink technic and appear as a large clear zone surrounding the chains frequently several times the diameter of the cocci

Capsulation in group B streptococci is quite different in nature and depends on the occurrence of type specific polysaccharides comparable with those elaborated by pneumococci

COLONY FORMS

The colonial characteristics of hemolytic streptococci are usually studied on the surface of blood agar plates so that the pattern of hemolysis and colony morphology can be observed simultaneously The size the distinctness and the rate of development of the zone of hemolysis surrounding surface colonies vary considerably Some strains notably certain members of groups C and D produce unusually large and brilliant zones while others may show no more than a narrow ring of hemolysis surrounding the colony The species of blood used in the agar medium influences the nature of the hemolysis and streptococci occur which give clear hemolysis with one mammalian blood but cause no hemolysis or only greening with others

Not all streptococci which fall into the recognized serologic groups produce hemolysis on the surface of blood agar plates Thus certain members of groups B C D H K and O and all members of group N are essentially nonhemolytic Even among group A strains variants occur which lack the ability to produce or release streptolysin S and thus are nonhemolytic under the aerobic conditions of surface growth Variants of this type are being encountered with increasing frequency on routine throat cultures leading to some difficulty in the initial recognition of pathogenic strains Such strains possess the colonial morphology of typical group A strains and produce the oxygen labile streptolysin O so that they become hemolytic when grown anaerobically or as deep colonies in agar pour plates

Isolated colonies of streptococci on blood agar average 1 to 2 mm in diameter The so called minute streptococci including members of groups F and G form much smaller colonies The topography of the colonies does not follow a single well-defined pattern they are usually circular in outline with smooth or slightly serrated edges and a rounded surface

Among group A streptococci several different colony forms are recognized and the descriptive terms most commonly employed are mucoid matt and glossy The mucoid character is associated with the production of hyaluronic acid capsules and the most strikingly mucoid strains are those that form abundant amounts of polysaccharide with large well-developed capsules Mucoid colonies are observed most satisfactorily on fresh blood agar plates or plates that have been sealed to prevent loss of moisture They tend to be large and glistening and may have the appearance of droplets of water (Fig 1 A) although when touched with a loop the viscous character of the colony is readily apparent The suggestion of fluidity is increased by the fact that the colonies frequently do not retain a circular shape The hyaluronate gel often collapses as a result of drying enzymatic action or chemical effect leaving a flattened colony with an irregular surface (Figs 1 B and C) It is these colonies that are currently referred to by the term matt although they might more appropriately be designated as "postmucoid

Glossy colonies are formed by strains that do not produce capsules during growth on agar These nonmucoid colonies are smaller and usually more rounded than the mucoid forms and they tend to have a shiny reflecting surface (Fig 1 D) The importance of the capsule in colony form is illustrated by the fact that strains such as those shown in Figures 1 A to C produce typical glossy colonies when grown in the presence of hyaluronidase

There is a limited relationship between colony form and production of antigenic constituents responsible for type specificity and

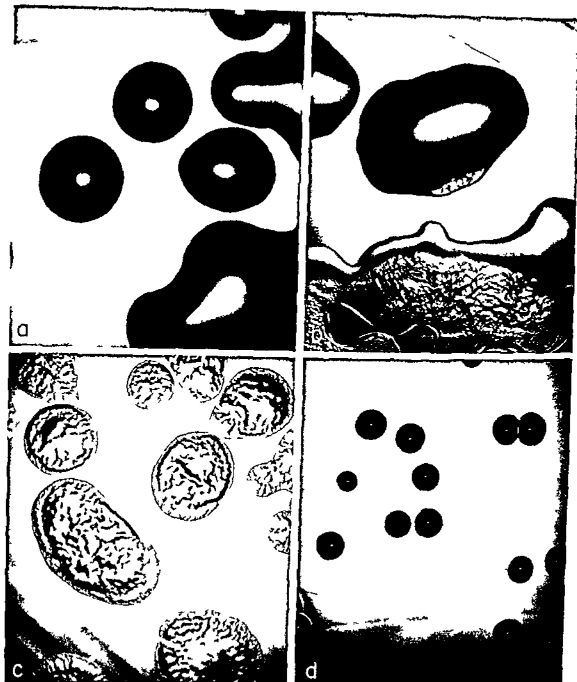

FIG 1 Colony forms of group A streptococci Magnification 5 5 × a Mucoid colonies b Mucoid colonies with beginning conversion to post mucoid state c Postmucoid colonies d Nonmucoid (glossy) colonies (Photographs from Dr A T Wilson Alfred I du Pont Institute of the Nemours Foundation Wilmington Delaware)

ing the colonies formed when dilutions of the culture are incorporated in an appropriate agar medium In the case of streptococci this procedure provides an estimate not of the number of individual viable cells but of the number of intact chains

Capsule formation is characteristic of many group A streptococci and capsules of similar

the amount of growth significantly The reducing conditions necessary for the initiation of growth in these media are usually obtained by the addition of a sulfhydryl compound such as cysteine or thioglycollate

There is a certain amount of evidence to suggest that the missing substances which account for the inadequacy of defined media are peptide in nature The substance designated streptogenin (Woolley 1941) which was found to be necessary for the growth of certain group A streptococcal strains is apparently a family of peptides rather than a single substance Others have found that peptide preparations are stimulatory to the growth of group A streptococci in defined media (Slade 1954)

Theoretically investigation of the extracellular enzymes and toxins of group A streptococci would be carried out most satisfactorily with defined media because of the absence of macromolecular constituents not arising from the organisms However these media have proved to be generally unsatisfactory for this purpose and the alternative approach of employing only the dialyzable components of complex meat infusion peptone media has been adopted (Stock 1939 Dole 1946) Most strains grow well and produce the expected complement of extracellular substances in appropriate dialysate media

The hemolytic streptococci are facultative anaerobes and metabolize glucose with the formation of lactic acid The accumulation of lactic acid with the attendant fall in pH is a limiting factor in the growth of the organisms in an otherwise adequate medium as indicated by the fact that massive growth can be obtained in the presence of excess glucose if the lactic acid formed is continuously neutralized Growth is optimal at 37 C and is markedly inhibited at temperatures above 40 C

GROUP DIFFERENTIATION

The division of hemolytic streptococci into serologic groups depends on the occurrence of group specific cellular antigens which are carbohydrate in nature and are designated as C carbohydrates (Lancefield 1928b 1933) The presence of these antigens is demonstrated by means of precipitin reactions between solutions of the carbohydrate extracted from streptococcal cells and antisera prepared by immunizing rabbits with heat killed suspensions of streptococci Lancefield showed that separating hemolytic streptococci into distinct categories by this technic resulted in a classification related to the most characteristic source of the organisms Thus group A is composed of strains usually pathogenic for man group B of strains from bovine mastitis group C is commonly found in streptococcal diseases of lower animals etc The source and the characteristics of the common serologic groups—including those that have been added since the initial studies of Lancefield—are summarized in Table 1 The relationship between group specificity and habitat is not a rigid one Thus although group A strains are responsible for most human streptococcal infections occasionally representatives of all other groups may be isolated from human sources

The serologic groups listed in Table 1 embrace the great majority of strains of hemolytic streptococci However additional strains are encountered which possess the general properties of hemolytic streptococci but do not fall into any of the defined groups

Information concerning the cellular localization and the chemical composition of the group specific carbohydrates has been obtained in recent years In the case of group A streptococci the carbohydrate is an integral component of the bacterial cell wall and may account for as much as 10 per cent of the dry weight of the organism (McCarty 1952 Salton 1953) The same localization has been shown to hold for several other groups (B C G and E) and the presence of rhamnose as a major monosaccharide in the cell wall of all major groups of streptococci indicates a uniform pattern which supports the concept of a basic interrelationship between the hemolytic streptococci (Cummins and Harris 1956 Slade and Slamp 1962) Variations in the content of hexosamines and other monosaccharides in the cell wall of different groups provide an adequate chemical basis for serologic differences

The group D streptococci stand as an important exception since the group specific antigen in these organisms has been identified as a member of the family of glycerol

TABLE 1 SUMMARY OF RECOGNIZED SEROLOGIC GROUPS OF STREPTOCOCCI

GROUP	USUAL HABITAT	USUAL PATHOGENICITY
A	Man	Many human diseases
B	Cattle	Mastitis
C	Many animals	Many animal diseases
	Man (human strains)	Mild respiratory infections
D	Dairy products	Genitourinary tract infections endocarditis wound infections
	Intestinal contents of man and animals (enterococci)	
E	Normal milk	None known
	Swine	Pharyngeal abscesses of swine
F	Man	Questionable found in respiratory tract
G	Man	Mild respiratory infections rare
	Dogs	Genital tract infections in dogs
H	Man	Questionable found in respiratory tract
K	Man	Questionable found in respiratory tract
L	Dogs	Genital tract infections
M	Dogs	Genital tract infections
N	Dairy products	None
O	Man	Occur in upper respiratory tract but not associated with disease Endocarditis

Groups A to E were described by Lancefield (1933) groups F and G by Lancefield and Hare (1935) groups H and K by Hare (1935) and groups L and M by Fry (unpublished) Group N was identified independently by several groups and the letter N was assigned by Shattock and Mattick (1943) Group O was described by Boissard and Wormald (1950)

virulence Strains that produce mucoid colonies usually elaborate M protein and are potentially virulent while those that produce glossy colonies often contain little or no M protein and are of low virulence However there are many exceptions to this relationship and colony form cannot be used as a reliable indication of either M protein production or potential virulence Thus nonvirulent strains can produce hyaluronic acid and give mucoid colonies and M protein may be produced by organisms which form typically glossy colonies These relationships have been discussed in detail by Wilson (1959)

Other more subtle differences in colony topography between strains of group A streptococci can be demonstrated when the organisms are grown on special media and examined at higher magnification but the basis for these differences is not yet established

GROWTH REQUIREMENTS

The pathogenic hemolytic streptococci are among the most fastidious of microorganisms in growth requirements As a routine procedure they are usually cultivated in complex media composed of peptone meat infusion salts and glucose Heating may reduce the ability of a medium to support growth and the best results are obtained when the broth is sterilized by filtration With even the most satisfactory media of this type further enhancement of growth usually can be achieved by the addition of blood or serum The effect of blood or serum is especially striking in the case of solid media since the growth of streptococci on the surface of agar plates tends to be quite poor in the absence of these additives

Some information concerning the minimal requirements for the growth of group A streptococci has been obtained by the use of chemically defined media (Bernheimer *et al* 1942 Slade *et al* 1951) although very few strains will grow vigorously and reproducibly under these conditions The findings indicate that up to 15 amino acids and almost all of the known members of the vitamin B complex are needed In addition purines and pyrimidines are required for certain strains and asparagine and glutamine may increase

different methods have been employed for this purpose (1) Extraction of cells at pH 2 and 100 C (Lancefield 1928a b) This method has the distinct advantage of simul taneously providing M protein containing ex tracts suitable for typing of group A strains (2) Extractions of cells with formamide at 160 to 180 C (Fuller 1938) (3) Lysis of streptococci with enzymes derived from *Streptomyces albus* (Maxted 1948) The cell wall is actually dissolved by this proce dure consequently the highest yields of car bohydrate are obtained (4) Autoclaving of suspensions of cells at 15 pounds pressure for 15 minutes (Rantz and Randall 1955) Characteristically solutions of the carbohy drate react rapidly with specific antisera to give floccules of antigen antibody precipitate and show little or no cross reaction with heterologous group antisera Thus with an appropriate supply of antisera the serologic group of unknown strains can be quickly determined The glycerol teichoic acid anti gens are also released in serologically active form by these several methods

Serologic grouping can also be achieved without extraction of the antigen by appli cation of the fluorescent antibody technic (Moody *et al* 1958) When carried out with reliable reagents and adequate controls on streptococci isolated from throat cultures this procedure gives results comparable with those obtained by the precipitin test

A nonserologic method of differentiating group A from the other groups of strepto cocci has been suggested by Maxted (1953) Group A strains were shown to be signifi cantly more sensitive to bacitracin than strains of all other groups and by choosing the appropriate concentration of the anti biotic Maxted devised a simple plate method for tentative identification of group A strains In a survey of a large series of strains the accuracy of this technic proved to be very high although rare exceptions were encoun tered

Streptococcal bacteriophages have been known for many years but the earlier studies were carried out for the most part without reference to serologic grouping Recent studies have shown that several group A phages are related serologically to one an other but distinct from group C phage fur thermore that susceptibility of streptococci of these two groups is primarily a group specific phenomenon (Krause 1957) al though other factors influence the suscepti bility of group A strains (Maxted 1955) The cell wall carbohydrate of group C strains inactivates group C phage suggesting that the group specific carbohydrate may serve as a phage receptor site in this case but no similar effect can be demonstrated with group A carbohydrate Also of interest with respect to the cell wall structure of streptococci is the fact that phage lysates of group C strep tococci contain a lytic factor presumably an enzyme which is highly active on group A and group E strains as well as on group C (Maxted 1957 Krause 1957) This en zyme dissolves the cell wall with release of the group specific carbohydrate in much the same way as the *Streptomyces albus* en zymes

ANTIGENIC AND BIOCHEMICAL COMPOSITION OF GROUP A STREPTOCOCCI

Because of the importance of group A streptococci in human infections the com position of these organisms has been studied in great detail Of particular importance are the several surface antigens and the wide variety of extracellular products which are released into the environment during growth Not all of these antigens are limited in their occurrence to group A streptococci and sub- stances similar to or identical with certain of these components are produced by some members of other groups

Surface Antigens

The properties of the several surface com ponents of streptococci are summarized in Table 2 Most of these are antigenic but the nonantigenic substances in the surface complex are included to provide a complete picture

Group specific Carbohydrate As noted above the group A carbohydrate is the major component of the bacterial cell wall The monosaccharide constituents are rhamnose and N acetyl glucosamine in a ratio of ap proximately 2 1 (Schmidt 1952 McCarty 1952 Salton 1953) When the carbohy

TABLE 2 SURFACE COMPONENTS OF STREPTOCOCCI

	COMPOSITION	DISTRIBUTION	SIGNIFICANCE
Capsule			
Hyaluronic acid	Repeating polymer of N acetyl glucosamine and glucuronic acid	Capsular material in most strains of group A and some of group C	Antiphagocytic effect under certain conditions Human serum contains factor counteracting this effect
Polysaccharide	Complex polysaccharides	Capsular material in group B	Type specific antigens in group B with antiphagocytic effect
Cell Wall			
M proteins	Protein	Type specific antigen on surface of cell wall in group A	Primary factor in virulence of group A streptococci through antiphagocytic effect
T & R proteins	Protein	Also on surface of cell wall of group A strep Analogous proteins probably occur in other groups (e g groups C and G)	No demonstrable role in virulence Participate in agglutination reactions
Carbohydrate	Polysaccharides with rhamnose as prominent component in most groups Hexosamines and often hexoses also present	Integral part of insoluble cell wall probably lying under surface proteins	Group specific antigens of groups A B C E and G (and probably others)
Mucopeptide	Polymer of N acetyl glucosamine and N acetyl muramic acid with peptides attached through carboxyl of muramic acid	Inner layer of cell wall Similar in all groups and in other bacteria	Rigid skeletal framework of cell wall
Glycerol teichoic acids	α Glycerophosphate polymers with additional substituents (sugars D alanine)	Localization unknown Not attached to wall by primary bonds but near surface of cell	Group specific antigens in groups D and N Heterophile antigen present in most groups
Cell membrane	Complex lipoprotein structure	Underlies cell wall	Limiting membrane in L forms and protoplasts Site of synthetic mechanisms for hyaluronic acid (and possibly other surface components)

teichoic acids which are not bound to the cell wall (Elliott 1962 Wicken *et al* 1963) In this instance the rhamnose containing carbohydrates of the cell wall have been designated as type specific antigens so that group D appears to comprise a rather diverse group of organisms all of which produce similar teichoic acids (Elliott 1960) This situation is not confined to a single group and the group-specific antigen of group N streptococci has also been identified as a glycerol teichoic acid

The occurrence of carbohydrate antigens as a part of the essentially insoluble cell wall structure explains the need for relatively drastic procedures in obtaining solutions of the carbohydrates It is necessary to bring about partial disintegration of the cell wall with the release of soluble carbohydrate in a form that retains its serologic reactivity In practice 4

protein is not a highly antigenic substance and prolonged immunization with suitable streptococcal vaccines is often necessary in order to produce adequate amounts of precipitating antibody The antisera obtained must be absorbed with organisms of heterologous types to remove antibodies to common streptococcal antigens which might give cross reactions Because of these considerations typing of streptococci is not widely used as a routine bacteriologic diagnostic procedure However it has proved to be of great importance in special clinical and epidemiologic studies

The detection of antibody to M proteins in human sera poses a special problem The ordinary in vitro tests such as the precipitin reaction are not sufficiently specific for this purpose since M antigen preparations contain other streptococcal substances which give rise to a high incidence of cross reactions As a result the measurement of type specific antibody has depended on complex biologic tests based on the role of the M antigen in virulence and phagocytosis For example it is often possible to demonstrate type specific protection with human sera in mouse infections but this procedure is somewhat insensitive and requires relatively large amounts of M antibody The most widely used procedure has been the so-called bactericidal test which exploits the fact that usually streptococci are rapidly killed following phagocytosis Streptococci containing M protein resist phagocytosis by human leukocytes and grow vigorously in normal blood However in the presence of type-specific antibody phagocytosis is greatly enhanced and virulent streptococci inoculated into blood if not present in excessive numbers can be completely destroyed by leukocytes Quantitative procedures for carrying out phagocytic tests have been devised and have been applied not only to the measurement of M antibody (Kuttner and Lenert, 1944 Rothbard 1945) but also to the antigenic analysis of streptococci (Maxted 1956 Lancefield 1957)

Because of the complexity of the phagocytic test other procedures have been sought for the measurement of type specific antibody Stollerman *et al* (1959) have shown that growth in the presence of M antibody significantly enhances the chain length of selected M-containing strains and have used this phenomenon in the measurement of type specific antibody Efforts have been made to apply such methods as passive hemagglutination in which tanned erythrocytes are treated with M extracts but it has been difficult to achieve specificity because of cross reacting antigens in the extracts which are common to many types of streptococci Some success has been reported recently in the elimination of these cross reactions by inhibition with heterologous extracts (Vosti and Rantz 1964)

Other Surface Protein Antigens In addition to the M protein there are other protein antigens which occur at or near the cell surface and apparently are attached to the cell wall Those which have been studied in detail and are characterized to some degree serologically and chemically have been designated T antigen and R antigen (Lancefield 1940 Lancefield and Perlmann 1952b)

T antigens are present in most strains of group A streptococci and as in the case of the M antigens they are represented by a large number of serologically distinct proteins (see summary in Lancefield 1954) However the distribution of T antigens is not directly related to that of the M antigens In some instances a common or closely related T antigen is found in several different specific M types For example types 15 17 19 23 30 and 47 appear to have closely related T antigens In addition within a single M type certain strains may have one T antigen while others have a totally unrelated T antigen and some strains may have no demonstrable T antigen

The T proteins are resistant to proteolytic digestion and serologically active preparations have been obtained in soluble form by extracting streptococci with proteolytic enzymes Because they are readily destroyed by heat at acid pH ordinarily these antigens are not represented in M-containing extracts Streptococci are agglutinated by antisera containing homologous T antibodies and T antigens have been studied most extensively by this technic Determination of T antigen by agglutination technics can occasionally be a useful adjunct in the identification of streptococci particularly in those cases where

drate is solubilized by the use of cell wall dissolving enzymes, purified preparations also contain muramic acid and amino acids characteristic of the mucopeptide structure found in all bacterial cell walls However the carbohydrate and the mucopeptide are independent elements of the wall and are separable by appropriate chemical technics (Krause and McCarty, 1961) The dominant serologic specificity of the carbohydrate appears to depend on terminal β N acetyl glucosamine residues on side chains or branches (McCarty 1956 1958) These terminal residues can be removed selectively by an induced enzyme obtained from a soil bacillus with concomitant loss of reactivity with group A antisera

In the course of passage of group A strains through animal hosts variants have been isolated which appear to have lost their group specific carbohydrates since extracts do not react with group A antisera (Wilson 1945 Lancefield and Perlmann 1952b) These variants contain a cell wall carbohydrate composed of the same monosaccharides as the group A carbohydrate but with a much higher ratio of rhamnose to N acetyl glucosamine Both the chemical and the serologic differences of the variant carbohydrate are explained by the total absence of terminal N acetyl glucosamine determinants on the side chains The chemical basis for reactivity of variant carbohydrate with homologous antisera is a rhamnose linkage which is also present in group A carbohydrate but is ordinarily masked by the terminal N acetyl glucosamine units (McCarty 1956)

Despite the fact that the group specific carbohydrate occurs near the surface of the cell in the cell wall it does not appear to participate vigorously in agglutination reactions of intact cells However fluorescein labeled antibody to the carbohydrate causes strong specific fluorescence of the entire surface of the cell Agglutination reactions have been shown to be dependent on protein antigens occurring at the cell surface

Soluble preparations of the carbohydrate have little toxicity for animals and are rapidly and quantitatively excreted by the kidney However Schwab *et al* (1959) have shown that cell wall fragments obtained by sonification and composed of the carbohydrate and the mucopeptide elements cause relapsing nodular lesions in the skin of the rabbit.

M Protein *The M proteins are the most* important of the surface proteins They are the antigens which determine the type specificity of group A streptococci and in addition they have been shown to be an important factor in virulence Their role in virulence is comparable with that of the capsular polysaccharides in the virulence of pneumococci That is they serve to inhibit phagocytosis of the organisms by host leukocytes and this antiphagocytic effect is nullified by specific antibody There are more than 40 recognized types of group A streptococci each characterized by a serologically distinct M protein It is indicated both by animal experiments and by observation of natural human infections that protective immunity is directed against the M protein and is therefore type specific The M proteins are firmly attached to the cell surface After mechanical disintegration of streptococci they remain associated with the isolated cell walls Removal of the protein in a soluble and serologically active form from either the intact cell or the cell wall is usually accomplished by the relatively drastic procedure of boiling at pH 2 However enzymatic dissolution of the cell wall in the absence of proteolysis e g with the lytic factor in group C phage lysates releases M protein in a comparable form

The M proteins of the various types of group A streptococci have many properties in common such as their resistance to heat in acid solution and their great susceptibility to proteolytic digestion The susceptibility of M protein to proteolytic enzymes is a property of the native protein and not dependent on previous treatment with acid and heat since it has been shown that this antigen can be destroyed by trypsin treatment of viable streptococci without killing the cells (Lancefield 1943) This fact provides additional evidence for the localization of M protein at the surface of the cell

The typing of group A streptococci is accomplished best by means of a precipitin reaction between an M containing extract of the organism and type specific rabbit antiserum Of necessity this means that there must be available a collection of a large number of different antisera Unfortunately M

TABLE 3 EXTRACELLULAR PRODUCTS OF GROUP A STREPTOCOCCI

	INHIBITION BY SPECIFIC ANTIBODY	DISTRIBUTION	COMMENT
Erythrogenic toxin	+	Produced by majority of strains	Evidence for at least 3 serologically different toxins Production shown to be dependent on infection with temperate bacteriophage in case of Toxin A
Streptolysin S	–	Produced by most strains	Probably cell bound to large extent Released from cell in combination with serum albumin or polyribonucleotides
Streptolysin O	+	Produced by most strains	Active in reduced state only
Diphosphopyridine nucleotidase	+	Production more common among some serologic types than others	
Streptokinase	+	Produced by most strains	
Deoxyribonuclease A	+	One or more produced by all strains	Four serologically distinct enzymes which attack the same substrate
" B	+		
C	+		
D	+		
Hyaluronidase	+	Produced by most members of types 4 & 22 Found only in minute amounts during in vitro growth of other strains	Production enhanced by presence of substrate
Streptococcal proteinase and precursor	+	Produced by majority of strains	Precursor usually found only at pH 5 5 to 6 5 Spontaneous activation under reducing conditions
Amylase	?	Variable but produced by many strains	Production enhanced by presence of substrate
Esterase	–	Produced by most strains	

glycerophosphate isolated from these organisms also react with extracts of most other groups of streptococci as well as those of certain other gram positive bacteria (McCarty 1959) The serologic specificity of this heterophile antigen is dependent on glycerophosphate determinants but in other cases as in the group D and N antigens substituent groups are the primary determinants of specificity The biologic significance of the glycerol teichoic acids remains obscure

L FORMS AND PROTOPLASTS

Typical L forms of group A streptococci were first isolated by Sharp (1954) by anaerobic growth of the organisms on a hypertonic agar medium in the presence of penicillin It was shown by chemical and serologic technics that these L forms lack components characteristic of the cell wall (Sharp *et al* 1957) Following the pioneering work of Weibull on other bacteria, streptococcal protoplasts were later prepared by enzymatic removal of the cell wall in a hypertonic environment that prevented osmotic rupture (Gooder and Maxted 1958 Freimer *et al* 1959) The L forms and the protoplasts are quite similar in their properties and represent forms free of cell wall obtained by two different procedures

Protoplasts of group A streptococci have one unusual property that is not common in the protoplasts of other bacterial species in

little or no M antigen appears to be present However since the T antigens have no known relationship to virulence or protection, identification of this component does not have the same significance as determination of the specific M type

The R antigens represent a third class of surface proteins of group A streptococci which can participate in agglutination reactions The first protein in this category was encountered in type 28 strains and was originally confused with the type specific antigen (Lancefield and Perlmann 1952b) The type 28R antigen resists tryptic digestion but is destroyed by pepsin and it is only slowly destroyed by heat and acid pH Three distinct M types (types 2 28 and 48) have been shown to produce the same R protein (Lancefield 1957) A second R antigen has been found to occur in type 3 strains but so far has not been demonstrated in strains of any other type (Lancefield 1958) The distinction between R and T antigens is not entirely sharp being based primarily on their relative susceptibility to proteolytic digestion and heating in acid and together they form a category of surface proteins which have no detectable relationship to virulence

In view of the complexity of the antigenic structure of group A streptococci it seems probable that there are other as yet unidentified surface antigens However the extensive serologic studies suggest that the M T and R antigens are the most prominent representatives of this class

Hyaluronic Acid Capsule Several independent attempts to demonstrate antigenicity of streptococcal hyaluronate have resulted in failure Despite the apparent nonantigenicity of this substance it is appropriate to consider it with the other surface constituents of the cell because of its peripheral distribution In its native state it is a mucopolysaccharide of high molecular weight which forms highly viscous solutions and is composed of equimolar quantities of N acetyl glucosamine and glucuronic acid It does not appear to be distinguishable chemically from mammalian hyaluronate a fact which may have some bearing on its lack of antigenicity

As indicated in the discussion of morphology of the streptococcal cell in young cultures the hyaluronate surrounds the organism in a well defined capsular structure As growth proceeds the capsules tend to diminish or disappear and the hyaluronate is found in solution in the medium In general the environment provided by host tissues appears to promote capsule formation so that the behavior of capsules in vivo may be quite different from that observed in artificial media

The role of the hyaluronate capsule in virulence is not altogether clear, but there is some evidence that it may help to protect the organism from phagocytosis and destruction and thus potentiate the antiphagocytic effect of the M protein In the case of mouse infections with encapsulated group C streptococci a marked degree of protection can be achieved by treating infected animals with hyaluronidase With group A strains the effect of hyaluronidase treatment of mouse infection is much less dramatic and protection is observed only when very low infecting doses are employed This is in contrast with the marked protective action of type specific anti M serum (Rothbard 1948) The relative importance of hyaluronate and M protein in natural infections of man has not been determined directly although here again it appears probable that the M protein plays a dominant role Studies with in vitro phagocytic systems indicate that normal human serum contains a factor which neutralizes the antiphagocytic effect of hyaluronic acid thus providing an explanation for the limited role of the capsule in human infections (Hirsch and Church 1960, Stollerman 1963)

Glycerol Teichoic Acids As noted above the group-specific antigens of group D and N streptococci belong to the family of bacterial substances designated as glycerol teichoic acids Basically these are polymers of glycero phosphate joined by 1 3 phosphodiester linkages with additional substituents through the hydroxyl at position 2 of the glycerol The most common of these substituents are ester linked D alanine and monosaccharides or oligosaccharides In streptococci these antigens are not bound to the cell wall but nonetheless appear to be present in the surface complex They are much more widely distributed than might appear from their designation as the group specific antigens of groups D and N and rabbit antisera to group A streptococci which react with a poly

TABLE 4 DIFFERENCES IN PROPERTIES OF STREPTOLYSIN O AND S*

	STREPTOLYSIN O	STREPTOLYSIN S
Activation by SH compounds	+	−
Neutralization by specific antibody	+	−
Release enhanced by serum or by polyribonucleotide	−	+
Trypsin sensitivity	+	−
Inhibition by low concentrations of cholesterol	+	−
Inhibition by low concentrations of lecithin	−	+
Rate of lysis	Not directly proportional to lysin concentration	Directly proportional to lysin concentration
Induction period prior to lysis	Short	Long

* Adapted from Bernheimer 1954

of the effects of toxin by antibody is further demonstrated by the fact that the intradermal injection of potent antitoxic sera will result in blanching of the rash in the early stages of scarlet fever (Schulz and Charlton 1918)

The erythrogenic toxins produced by all strains of group A streptococci are not identical Thus Coffey (1938) in a survey of a large number of strains found that the toxins of about 80 per cent were neutralized by a single antitoxic serum while most of the remaining 20 per cent were neutralized by one or the other of two additional antisera The existence of serologically distinct erythrogenic toxins clarifies some of the irregularities observed in reversal of the Dick test after scarlet fever and also provides a rational explanation for the occurrence of second attacks of the disease

Recent evidence (Zabriskie 1964) indicates that the production of erythrogenic toxin by streptococci is associated with the lysogenic state—i e the infection of the organism with certain temperate bacteriophages—in the same way that lysogeny is involved in the production of diphtheria toxin Strains of group A streptococci which do not release detectable toxin can be converted to toxin production by infection with temperate bacteriophages derived from known toxinogenic strains thus providing an explanation for the transmissible toxigenicity first described by Frobisher and Brown (1927) The induction of phage replication and release by ultraviolet irradiation is associated with a sharp increase in the amount of erythrogenic toxin appearing in the culture medium

Preparations of erythrogenic toxin have been obtained in a concentrated and partially purified state with potencies as high as 10^8 skin test doses per μg N (Stock 1939) Progress in the study of the toxin has been limited by the crude nature of the assay procedure which depends on the rather non specific erythematous skin reaction However it is clear that different strains of streptococci vary in the amount of toxin produced in artificial media and the differences are great enough to suggest that they may play a role in the variability of the occurrence of scarlet fever in different epidemics of streptococcal disease Certain strains of group C and group G streptococci have been found to produce a toxin with similar properties

Streptolysin S This agent is responsible for the zones of hemolysis which surround streptococcal colonies on the surface of blood agar plates The designation S refers to serum and derives from the fact that the hemolysin appears to be extracted from living streptococci when they are shaken with serum (Todd 1938) Subsequently Okamoto (1939) found that yeast ribonucleic acid is highly active in inducing release of a hemolysin which appears to be identical with streptolysin S Detailed studies of this material have been made by Okamoto and by Bernheimer (see review by Bernheimer 1954) Recent studies by Ginsburg *et al* (1963) suggest that streptolysin S is in large

that they will proliferate to form colonies in hypertonic agar medium The colonies formed are typical of L-forms, and their growth is unaffected by penicillin in high concentration Despite the absence of the cell wall these forms continue to produce M protein during growth but the antigen is released into the medium rather than being retained on the cell surface In addition, certain of the characteristic extracellular products deoxyribonuclease and a hemolysin can be demonstrated in the agar medium in which protoplasts are grown Adaptation to growth in fluid media has proved to be difficult although it has been achieved with a few strains of L-forms

The cell membrane obtained after osmotic lysis of protoplasts is a lipoprotein structure quite distinct from the cell wall in composition (Freimer 1963) It contains antigens not present in the wall or the cytoplasm and there is preliminary evidence for distinctive antigenic differences between the membranes of different groups of streptococci The finding offers a possible means of identifying L forms isolated from human materials The ability of cell wall free forms of streptococci to survive in vivo and their possible pathogenic significance remain to be explored

Markovitz and Dorfman (1962) have shown that hyaluronic acid can be synthesized from uridine nucleotide intermediates with enzymes present in the protoplast membrane It seems likely the enzymatic systems for the synthesis of other surface components will also be found in the membrane

Extracellular Products of Group A Streptococci

Group A streptococci elaborate a wide variety of biologically active substances including toxins and enzymes which accumulate in the culture medium during growth Not all of these extracellular products are produced simultaneously by any single strain but most strains are capable of forming a majority of them It is known that environmental conditions exert a profound effect on the production of certain of the extracellular substances consequently their occurrence in infected host tissues may differ from that observed in artificial media However since specific antibodies to most of these substances can be found in the sera of patients convalescing from streptococcal infections it is evident that the organisms retain the ability to produce them under in vivo conditions

The list of the known extracellular products (Table 3) probably falls far short of representing the total capacity of group A streptococci in this regard This is indicated not only by the fact that new substances continue to be discovered but also by the results of serologic and electrophoretic studies of concentrated culture fluids which suggest that the known substances can account for only a fraction of the streptococcal protein present

The extent to which the various extracellular substances contribute to the pathogenicity of hemolytic streptococci can for the most part only be surmised since it is difficult to evaluate the importance of a single enzyme or toxin in the over all interaction between parasite and host tissues However on general biologic grounds it seems likely that they are useful to the survival of the organism in its natural habitat which must be assumed to be human tissues The properties of the extracellular substances are discussed in the following sections

Erythrogenic toxin is the substance responsible for the characteristic skin rash of scarlet fever Its mode of action is unknown and the only assay procedure available for the study of the toxin filtrates of streptococcal cultures is a skin test depending on intracutaneous injection of the material in humans (Dick test 1924) or certain susceptible animals The potency of the toxin is such that culture filtrates of appropriate strains can be diluted 100 fold or more and thus the nonspecific irritating effect of other substances in the broth usually can be avoided A positive Dick test is an erythematous and often edematous area of more than 10 mm diameter which appears within 6 to 24 hours

The effects of the toxin are neutralized by antibody A susceptible child shows a positive Dick test and this reactivity persists during the acute phase of scarlet fever However after convalescence the skin test becomes negative in the vast majority of patients as the result of antibody formation Inhibition

TABLE 4 DIFFERENCES IN PROPERTIES OF STREPTOLYSIN O AND S*

	STREPTOLYSIN O	STREPTOLYSIN S
Activation by SH compounds	+	−
Neutralization by specific antibody	+	−
Release enhanced by serum or by polyribonucleotide	−	+
Trypsin sensitivity	+	−
Inhibition by low concentrations of cholesterol	+	−
Inhibition by low concentrations of lecithin	−	+
Rate of lysis	Not directly proportional to lysin concentration	Directly proportional to lysin concentration
Induction period prior to lysis	Short	Long

Adapted from Bernheimer 1954

of the effects of toxin by antibody is further demonstrated by the fact that the intradermal injection of potent antitoxic sera will result in blanching of the rash in the early stages of scarlet fever (Schulz and Charlton 1918)

The erythrogenic toxins produced by all strains of group A streptococci are not identical Thus Coffey (1938) in a survey of a large number of strains found that the toxins of about 80 per cent were neutralized by a single antitoxic serum while most of the remaining 20 per cent were neutralized by one or the other of two additional antisera The existence of serologically distinct erythrogenic toxins clarifies some of the irregularities observed in reversal of the Dick test after scarlet fever and also provides a rational explanation for the occurrence of second attacks of the disease

Recent evidence (Zabriskie 1964) indicates that the production of erythrogenic toxin by streptococci is associated with the lysogenic state—i e the infection of the organism with certain temperate bacteriophages—in the same way that lysogeny is involved in the production of diphtheria toxin Strains of group A streptococci which do not release detectable toxin can be converted to toxin production by infection with temperate bacteriophages derived from known toxinogenic strains thus providing an explanation for the transmissible toxigenicity first described by Frobisher and Brown (1927) The induction of phage replication and release by ultraviolet irradiation is associated with a sharp increase in the amount of erythrogenic toxin appearing in the culture medium

Preparations of erythrogenic toxin have been obtained in a concentrated and partially purified state with potencies as high as 10^6 skin test doses per μg N (Stock 1939) Progress in the study of the toxin has been limited by the crude nature of the assay procedure which depends on the rather nonspecific erythematous skin reaction However it is clear that different strains of streptococci vary in the amount of toxin produced in artificial media and the differences are great enough to suggest that they may play a role in the variability of the occurrence of scarlet fever in different epidemics of streptococcal disease Certain strains of group C and group G streptococci have been found to produce a toxin with similar properties

Streptolysin S This agent is responsible for the zones of hemolysis which surround streptococcal colonies on the surface of blood agar plates The designation S refers to serum and derives from the fact that the hemolysin appears to be extracted from living streptococci when they are shaken with serum (Todd 1938) Subsequently Okamoto (1939) found that yeast ribonucleic acid is highly active in inducing release of a hemolysin which appears to be identical with streptolysin S Detailed studies of this material have been made by Okamoto and by Bernheimer (see review by Bernheimer 1954) Recent studies by Ginsburg *et al* (1963) suggest that streptolysin S is in large

that they will proliferate to form colonies in hypertonic agar medium The colonies formed are typical of L-forms and their growth is unaffected by penicillin in high concentration Despite the absence of the cell wall these forms continue to produce M protein during growth but the antigen is released into the medium rather than being retained on the cell surface In addition certain of the characteristic extracellular products deoxyribonuclease and a hemolysin can be demonstrated in the agar medium in which protoplasts are grown Adaptation to growth in fluid media has proved to be difficult although it has been achieved with a few strains of L forms

The cell membrane obtained after osmotic lysis of protoplasts is a lipoprotein structure quite distinct from the cell wall in composition (Freimer, 1963) It contains antigens not present in the wall or the cytoplasm and there is preliminary evidence for distinctive antigenic differences between the membranes of different groups of streptococci The finding offers a possible means of identifying L forms isolated from human materials The ability of cell wall free forms of streptococci to survive in vivo and their possible pathogenic significance remain to be explored

Markovitz and Dorfman (1962) have shown that hyaluronic acid can be synthesized from uridine nucleotide intermediates with enzymes present in the protoplast membrane It seems likely the enzymatic systems for the synthesis of other surface components will also be found in the membrane

Extracellular Products of Group A Streptococci

Group A streptococci elaborate a wide variety of biologically active substances including toxins and enzymes which accumulate in the culture medium during growth Not all of these extracellular products are produced simultaneously by any single strain but most strains are capable of forming a majority of them It is known that environmental conditions exert a profound effect on the production of certain of the extracellular substances consequently their occurrence in infected host tissues may differ from that observed in artificial media However since specific antibodies to most of these substances can be found in the sera of patients convalescing from streptococcal infections it is evident that the organisms retain the ability to produce them under in vivo conditions

The list of the known extracellular products (Table 3) probably falls far short of representing the total capacity of group A streptococci in this regard This is indicated not only by the fact that new substances continue to be discovered but also by the results of serologic and electrophoretic studies of concentrated culture fluids which suggest that the known substances can account for only a fraction of the streptococcal protein present

The extent to which the various extracellular substances contribute to the pathogenicity of hemolytic streptococci can for the most part only be surmised since it is difficult to evaluate the importance of a single enzyme or toxin in the over all interaction between parasite and host tissues However, on general biologic grounds it seems likely that they are useful to the survival of the organism in its natural habitat, which must be assumed to be human tissues The properties of the extracellular substances are discussed in the following sections

Erythrogenic toxin is the substance responsible for the characteristic skin rash of scarlet fever Its mode of action is unknown and the only assay procedure available for the study of the toxin filtrates of streptococcal cultures is a skin test depending on intracutaneous injection of the material in humans (Dick test 1924) or certain susceptible animals The potency of the toxin is such that culture filtrates of appropriate strains can be diluted 100 fold or more and thus the nonspecific irritating effect of other substances in the broth usually can be avoided A positive Dick test is an erythematous and often edematous area of more than 10 mm diameter which appears within 6 to 24 hours

The effects of the toxin are neutralized by antibody A susceptible child shows a positive Dick test and this reactivity persists during the acute phase of scarlet fever However after convalescence the skin test becomes negative in the vast majority of patients as the result of antibody formation Inhibition

and unrelated technics for inhibiting its bio logic activity oxidation cholesterol inhibi tion and inhibition by specific antibody Thus any property of a streptolysin O preparation which is nullified by all three technics can reasonably be assumed to be due to the hemolysin Using these technics Todd (1942) has presented evidence that streptol ysin O is toxic for leukocytes It has been shown to act as a lethal toxin on intravenous injection into a variety of laboratory animals and one possible explanation for its lethal action has come from studies of its cardio toxicity Bernheimer and Cantoni (1945) first demonstrated that streptolysin O in small amounts causes systolic standstill in the isolated frog heart More recently these studies (Kellner *et al* 1956) have been ex tended to a study of the mammalian heart The isolated hearts of rat rabbit and guinea pig all respond with irreversible loss of myo cardial contractility when as little as 25 to 50 hemolytic units of streptolysin O are added to the perfusion fluid Partially puri fied preparations of the hemolysin have been obtained with a potency as high as 33 000 hemolytic units per mg N and thus it is apparent that very minute amounts are suffi cient to exert a cardiotoxic effect

Halbert *et al* (1961) have extended these studies on cardiotoxicity of streptolysin O to the intact animal and have shown that death from lethal doses is consistently preceded by profound electrocardiographic changes

Diphosphopyridine Nucleotidase (DPN ase)* Streptococcal DPNase was discov- ered in the course of attempts to deter mine the mechanism of the cardiotoxic effect of streptolysin O on mammalian hearts The streptolysin O preparations used were found to inhibit certain of the metabolic enzymes of mammalian heart muscle (Carlson *et al* 1956) but this enzyme inhibition was not affected by any of the procedures known to inactivate the hemolysin Thus it was neces sary to attribute the effect to some unknown component of the preparation The key to its nature was provided by the fact that all of the enzyme systems inhibited involve the co enzyme DPN and direct test revealed the presence of a highly active DPNase which acts by liberating nicotinamide from the molecule (Carlson *et al* 1957)

Streptococcal DPNase is produced by a wide variety of group A strains although many are encountered which do not form appreciable amounts even when grown in the presence of serum a procedure which in creases the yield of the enzyme There appears to be some relationship between DPNase production and serologic type For example Lazarides and Bernheimer (1957) have found that all of 23 strains of type 3 and 52 of 58 strains of type 12 produce the enzyme while all of 33 strains of type 1 and 38 strains of type 19 do not Among other serologic groups certain strains of group C and G possess this property

The enzyme is antigenic and antibodies which inhibit its activity are found in the serum of patients convalescing from strepto coccal infections Ayoub and Wannamaker (1963) have described the occurrence in culture filtrates of a substance possibly an inactive form of the enzyme or a zymogen which binds antibody to DPNase This find ing must be taken into consideration in standardizing methods for the measurement of antibody

A possible toxic role for DPNase has been suggested as a result of studies of the phe nomenon of leukotoxicity This phenomenon first described by Levaditi (1918) years ago is manifested by sudden death and disintegra tion of leukocytes after the ingestion of streptococci Wilson (1957) has shown that certain streptococcal strains consistently exert this effect on a proportion of the leuko cytes which phagocyte them while others apparently lack the ability to injure the leukocyte In a collaborative study (Bern heimer Lazarides and Wilson 1957) involv ing 39 different streptococcal strains it has been found that there is an excellent corre lation between the ability of a strain to pro- duce DPNase and its leukotoxicity All but 2 of the DPNase positive and none of the DPNase negative strains proved to be leuko- toxic While these findings suggest that the enzyme may be concerned in the destruction of the leukocyte some form of direct con firmatory evidence will be needed to establish the relationship

Streptokinase The occurrence of a sub- stance in streptococcal culture filtrates which

* In the new terminology this enzyme is re- ferred to as nicotinamide adenine dinucleotidase (NADase)

part cell bound and that its release from the cell depends on association with some carrier molecule such as serum albumin or ribonucleic acid These observations would explain much of the anomalous behavior of this hemolysin

Partially purified preparations of streptolysin S induced with ribonucleic acid have been obtained with potencies as high as 390 000 hemolytic units per mg N (Bernheimer 1954) These preparations contain both protein and polynucleotide However the activity of the material is destroyed by certain proteolytic enzymes and the hemolytic activity is electrophoretically separable from the polynucleotide, so that it seems probable that streptolysin S is protein in nature Despite this fact the present evidence indicates that streptolysin S is not antigenic or at least that any antibodies formed are not able to neutralize its hemolytic action Inhibitory antibodies are not found in sera of immunized animals or of patients convalescing from streptococcal disease Earlier studies which suggested the occurrence of neutralizing antibody in low titer have been shown to depend on the nonspecific inhibitory effect of serum lipoprotein Phospholipids in the form of lipoprotein complexes appear to play the major role in this inhibition

Attempts to determine whether streptolysin S has toxic effects other than that represented by hemolysis of erythrocytes have been hampered by the fact that pure preparations are not available so it is not possible to be certain that any pharmacologic or pathologic effect observed is not due to some other substance present in the material Evidence for another biologic effect of the hemolysin has been supplied recently by Weismann *et al* (1963) who showed that preparations of both streptolysin S and O cause disruption of lysosomes of mammalian cells and release of lysosomal enzymes

The production of streptolysin S by groups of streptococci other than A has not been studied adequately, although it must be assumed that in most instances an analogous lysin is formed which is responsible for lysis on the surface of blood agar plates No systematic information is available on the effect of ribonucleic acid on the production of hemolysin by other groups

Streptolysin O This hemolysin is so designated because of its oxygen lability and is quite distinct from streptolysin S (see summary of comparative properties in Table 4) It is hemolytically inactive in the oxidized form but is readily activated by the addition of reducing agents such as sulfhydryl compounds This property of reversible oxygen lability is shared with certain other bacterial hemolysins e g , pneumolysin and tetanolysin It is responsible for the failure of streptolysin O to participate in the formation of hemolytic zones around colonies of streptococci grown aerobically on the surface of blood agar The reducing conditions which develop in the environment of deep colonies in blood agar pour plates are sufficient to activate the hemolysin Streptolysin O is produced by almost all strains of group A streptococci and strains which lack this property are encountered only rarely It is also formed by many strains of groups C and G

Streptolysin O has not been obtained in pure form but since it is readily destroyed by proteolytic enzymes it would appear to be protein in nature It is antigenic eliciting the formation of antibodies which effectively neutralize its hemolytic action A high proportion of patients with streptococcal infections show an antibody response during convalescence consequently the measurement of serum antistreptolysin O has become widely used as a test for establishing the occurrence of a recent streptococcal infection Both the oxidized and the reduced forms will combine with specific antibody indicating that reversible oxidation is not associated with major changes in the antigenic properties of streptolysin O Cholesterol is highly active as an inhibitor of streptolysin O For some reason the free cholesterol of normal serum does not exert an appreciable inhibitory effect and does not interfere with the measurement of specific antistreptolysin O However bacterially contaminated serum or serum subjected to certain kinds of chemical treatment may develop inhibitory activity as a result of changes in the lipoproteins

Despite the fact that streptolysin O has not been obtained in pure form study of its biologic effects has met with more success than in the case of streptolysin S This is made possible by the availability of three specific

first serologic studies on deoxyribonuclease (McCarty 1949) has been shown to produce predominantly deoxyribonuclease A and this accounts for the low incidence of antibody responses observed in patients There is little information on the possible diversity of groups C and G deoxyribonucleases although deoxyribonuclease A appears to be the most common enzyme in group C

The production by streptococci of 4 enzymes which attack the same substrate is of theoretic interest It is possible that each enzyme hydrolyzes a different specific linkage in the substrate macromolecule but comparative studies of the split products have not yet been made There is no evidence that deoxyribonuclease attacks living cells and thus it is unlikely that the streptococcal enzymes exert a deleterious effect on tissues during streptococcal infections However they are effective in hydrolyzing the nucleic acids and the nucleoproteins released by necrotic cells and the split products are apparently utilized by the microorganism indicating that the enzymes may have nutritional significance The effect of deoxyribonuclease on nucleoproteins has been exploited as a therapeutic tool in the liquefaction of highly viscous exudates which result from the disintegration of leukocytes as in the case of empyema Preparations containing streptokinase and deoxyribonuclease (streptodornase) from group C strains are commercially available and have been employed in a variety of conditions in which fibrinous or nucleoprotein-containing exudates accumulate (Tillett 1950)

Ribonuclease activity found in culture fluids of group A streptococci (McCarty 1948) is probably due to deoxyribonuclease B (Yasmineh *et al* 1963) Thus this enzyme possesses a rather unusual substrate specificity

Hyaluronidase The production of an extracellular hyaluronidase by an organism which is also able to elaborate a hyaluronic acid capsule would appear at first glance to present something of a paradox especially since it is known that the capsule is destroyed readily by the enzyme However in vitro studies indicate that streptococci rarely produce both substances simultaneously There fore the two functions are to some extent mutually exclusive although there is reason to believe that a single strain may produce capsules while growing under one set of conditions and hyaluronidase under different conditions Hyaluronidase accumulates in relatively large amounts in the culture fluids of most strains of type 4 and type 22 (Crowley 1944) and these strains are apparently never encapsulated Only rare strains of other types have been described as producing comparable amounts of hyaluronidase In the case of the majority of group A strains the presence of an extracellular hyaluronidase can be demonstrated if at all only by highly sensitive tests and often after prolonged incubation even with the use of these technics the amount produced is extremely small compared with that of types 4 and 22 strains The production of the enzyme by types 4 and 22 strains is enhanced by the addition of hyaluronate to the medium (Rogers 1945)

The results of antibody studies suggest that the in vitro findings do not reflect the true potentialities of group A streptococci with respect to hyaluronidase formation Following streptococcal infections a high percentage of patients show an increasing titer of antibodies which specifically inhibit hyaluronidase preparations obtained from types 4 or 22 strains It has been established that this is a true antibody and is not related to the nonspecific hyaluronidase inhibitors found in normal sera Since these antibodies are formed regardless of the type of streptococcus associated with the infection it seems obvious that the pattern of hyaluronidase production observed in laboratory studies is misleading and that most group A strains must produce hyaluronidase during infections in sufficient amounts to stimulate antibody production The explanation of this discrepancy remains obscure and it may involve the action of some undefined factor in the in vivo environment that stimulates production or activation of the enzyme

The understanding of hyaluronidase production by streptococci is further complicated by the finding of Kjems (1958) that this enzyme is also produced during the interaction of many bacteriophages with group A streptococci He believes that these latter enzymes are associated with the bac

promotes the lysis of human fibrin clots was first described by Tillett and Garner (1933) and the active agent was termed streptococcal fibrinolysin Subsequently, it was found (Milstone 1941) that fibrinolysis depends on the presence of an essential serum factor which was later identified as the inactive precursor of a proteolytic enzyme (Christensen 1945) The accumulated evidence indicates that the streptococcal substance exerts its effect by causing the activation of this precursor termed plasminogen and because of the similarity to the activation of trypsinogen by enterokinase the term streptokinase was suggested as more appropriate than fibrinolysin There is a possibility that streptokinase does not act directly on plasminogen but rather on a proactivator which in turn activates plasminogen This human plasma protease system is further complicated by the occurrence of natural inhibitors which affect both the activation process and the enzymatic activity of the protease

Streptokinase is a remarkably potent activator of the human protease system Partially purified preparations containing 2 000 fibrinolytic units per microgram of nitrogen, have been obtained by Christensen (1954) who estimates that as little as 0 00005 mcg of streptokinase nitrogen will exert a detectable effect on a fibrin clot In general it appears to be much less effective in the protease systems of other animal species This may depend on both quantitative and qualitative differences in plasminogen and inhibitors

The biologic activity is readily destroyed by trypsin suggesting that streptokinase is protein in nature It is antigenic and again the antibodies formed specifically inhibit its action The inhibitory effect of antibody can be clearly distinguished from the effects of natural inhibitors of the protease system, and methods have been devised for measuring the amount of antibody in human sera Increases in titer of specific antistreptokinase occur in a high percentage (70 to 80%) of patients following streptococcal infections

Strains of group A streptococci vary over a wide range in the amount of streptokinase produced when the organisms are grown under favorable conditions in artificial media but very few strains appear to lack this property completely Certain group C strains elaborate streptokinase in large amounts, and these have been used in large scale production of the substance which has been undertaken because of the therapeutic value of its fibrinolytic action It is also produced by some group G strains

The possible part that streptokinase plays in the pathogenesis of streptococcal infection is unknown and there is no clear indication that activation of the plasma proteolytic enzyme results in toxic effects or tissue damage However it seems inescapable that streptokinase must prevent the formation of an effective fibrin barrier and thus influence the character of lesions by interfering with localization of the infection

Deoxyribonuclease The supernatant fluid from the growth of certain streptococci can effect rapid depolymerization of deoxyribonucleic acid (Tillett *et al*, 1948, McCarty 1948) This deoxyribonuclease activity is found in cultures of all group A strains in readily detectable amounts and is also present in representatives of several other groups As in the case of many of the other extracellular streptococcal products strains of groups C and G are prominent among the latter

Group A streptococci produce 4 serologically distinct deoxyribonucleases, designated A B C and D (Wannamaker 1958 1962) The enzymes are separable by zone electrophoresis and each is magnesium activated and inhibited by versene Antibodies to the individual enzymes produced in rabbits inhibit the homologous enzyme but do not affect the activity of the others Serum from patients with rheumatic fever or convalescent from streptococcal infections also show marked differences in their ability to inhibit the 4 enzymes A high percentage of patients comparable with that observed in the case of antistreptolysin O produce inhibitory antibody to deoxyribonuclease B while the response to A C and D appears to be inconstant and irregular

Strains of group A streptococci vary in the relative amounts of the 4 enzymes elaborated Some strains produce all 4 enzymes but the predominant enzyme is usually deoxyribonuclease B a fact which is in accord with the serologic findings in patients The organism used in the preparation of enzyme for the

tococcal proteinase causes tissue damage in the course of streptococcal infections The re quirement of low pH and reducing conditions for the release of the enzyme suggests that it will be formed only in certain kinds of infec tion as for example in an abscess where the appropriate environment would be expected That the enzyme is capable of inducing tissue changes in experimental animals has been demonstrated by Kellner and Robertson (1954) who found that intravenous injection of activated streptococcal proteinase results in the formation of necrotic myocardial le sions in rabbits guinea pigs and mice This effect is also shown by other proteolytic en zymes and thus is not specific for strepto coccal proteinase

Amylase Many strains of group A strepto cocci elaborate an extracellular amylase when grown in the customary peptone media (Crowley 1950 1954) The enzyme has the properties of an α amylase and hydrolyzes glycogen and amylopectin in addition to starch Production of amylase varies greatly among strains and even individual members of a population of a single strain may show differences in enzyme activity The presence of substrate in the medium greatly enhances the amount of amylase released

Further studies have revealed that the same strains which produce amylase will under different cultural conditions synthe size a starchlike polysaccharide (Crowley 1955 Crowley and Jevons 1955) The presence of human plasma in the medium is important for the formation of the sub stance and maltose serves as an adequate sub strate although starch and glycogen are also effective These findings provide another ex ample of the marked influence of environ mental conditions on the biologic behavior of streptococci

The antigenicity of amylase and the pos sible occurrence of antibodies in human sera have not been investigated

Esterase Stock *et al* (1961) have de scribed the production by group A strepto cocci of an extracellular esterase which acts on the substrate β naphthyl acetate The antibody to this enzyme found in rabbit and human antisera does not inhibit the action of the enzyme

Intracellular Components

The intracellular components of group A streptococci have received little attention in comparison with that given to the surface constituents and extracellular products In part this is referable to the fact that cellular extracts represent highly complex mixtures which are difficult to resolve Such extracts contain a variety of proteins including the various metabolic and synthetic enzymes of the cell and large amounts of other material such as nucleotides and nucleic acids A nucleoprotein fraction obtained by extrac tion with weak alkali has been examined for its serologic properties (Lancefield 1925) Although this material probably makes up a large portion of the total cellular contents and must be very heterogeneous antigenically the serologic studies are useful in indicating interrelationships between bacterial species Thus nucleoproteins from hemolytic strepto cocci react with antisera from animals im munized with nucleoproteins from both hemolytic and nonhemolytic streptococci as well as with similar preparations obtained from pneumococci A lesser degree of cross reactivity was observed with antisera to staphylococcal nucleoproteins

The properties of individual cellular en zymes have been investigated in only a few instances Jacox (1953) reported the occur rence of a β glucuronidase which he found in representatives of only 4 of 32 different types of group A streptococci There was no evi dence of inhibition of the enzyme by the sera of patients convalescing from streptococcal infections The lipoproteinase described by Krumwiede (1954) which causes opal escence in serum by splitting α_1 lipoprotein probably represents a cellular enzyme since it is extractable from washed organisms with 40 per cent urea However it may be re leased into the environment under conditions reminiscent of those which affect the produc tion of streptolysin S that is it is found in serum broth cultures and appears to be ex tractable from cells with serum Preliminary studies suggest that certain human sera may contain antibodies which inhibit lipopro teinase and inhibitory antisera have been ob tained by immunizing rabbits with crude enzyme preparations

teriophage and are serologically distinct from the streptococcal hyaluronidase The relationship is therefore somewhat different from that observed in the case of erythrogenic toxin

Streptococcal hyaluronidase differs from testicular hyaluronidase in several respects The end products of hydrolysis by the bacterial enzyme are not identical with those of the mammalian enzyme and the former does not attack chondroitin sulfate

Hyaluronidase production occurs in streptococci other than those of group A notably in certain strains of groups B, C and G In the case of groups C and G it has been shown that the enzymes are serologically distinct from those of group A and are not significantly inhibited by antibody to the group A enzyme

Streptococcal Proteinase This enzyme and its inactive precursor are the only extracellular substances which have been obtained in crystalline form (Elliott 1950) They are also unique by virtue of the marked effect exerted by environmental conditions on their production Proteinase precursor is released by most strains of streptococci only when the pH of the medium is maintained between 5 5 and 6 5 Thus except in the case of certain unusual strains none of this substance is found under the optimal conditions for growth of the organisms between pH 7 0 and pH 8 0 which also favor the production of other extracellular enzymes As in the case of streptolysin S and deoxyribonuclease precursor is formed by washed streptococcal cells when suspended in an incomplete medium Salts and glucose are sufficient for this purpose if the pH is maintained below 6 5 but production is greatly enhanced by the addition of peptone products The capacity of streptococci to produce this substance under appropriate conditions appears to be much greater than for the other extracellular enzymes and Elliott (1950) reports the recovery of 169 mg of 6 times recrystallized material from 10 liters of culture filtrate

The precursor is autocatalytically converted to active proteinase under suitable reducing conditions (Elliott and Dole 1947) This conversion may occur in culture media if aerobic conditions do not prevent a fall in oxidation reduction potential and can be achieved in solutions of the crystalline precursor by the addition of sulfhydryl compounds or other reducing agents The autocatalytic effect appears to depend on the initial presence of traces of active enzyme The action of trypsin in low concentration also brings about rapid conversion of the precursor Formation of active enzyme by either method is accompanied by the release of dialyzable split products amounting to 40 per cent of the weight of crystalline precursor Streptococcal proteinase resembles cathepsins and plant enzymes of the papain family in requiring activation by sulfhydryl compounds or comparable reducing agents Studies on synthetic substrates indicate that it has an unusually broad substrate specificity (Myceк *et al* 1952)

The production of proteinase by streptococci appears to be largely limited to members of group A It has been found in representative cultures of most of the serologic types although enhancement of virulence by mouse passage results in suppression of its production (Elliott 1945) Growth of streptococci under conditions which allow the appearance of active proteinase in the medium can have a profound effect on other biologic properties Thus the M protein is destroyed because of its great susceptibility to proteolytic digestion and serologic typing of the organisms becomes impossible (Elliott 1945) Furthermore certain of the other extracellular products e g streptokinase and hyaluronidase may be destroyed by proteolytic action

Precipitating antibodies have been prepared in rabbits against both crystalline proteins The proteins differ serologically and the precursor behaves as though it has 2 antigenic components one of which is specific and the other identical with the proteinase antigen (Elliott 1950) Rabbit and horse antibodies to proteinase have been shown to inhibit the action of the enzyme However inhibitory antibodies are not readily demonstrated in sera of patients after streptococcal infections but it has been possible by the use of a hemagglutination technic to demonstrate that antibodies are produced by a large proportion of such patients (Ogburn *et al* 1958) It is not known whether or not strep

partum endometrium and septicemia of the newborn can be caused by these organisms

Hemolytic streptococcal infections are to be distinguished from infections associated with the various nonhemolytic streptococci which are found among the normal flora of the respiratory and the gastrointestinal tracts These organisms frequently find their way into the bloodstream in small numbers but under ordinary conditions they are readily disposed of by the natural defense mechanisms However in the presence of anomalies of anatomic structure they may become established as infectious agents Thus subacute bacterial endocarditis which affects heart valves altered by congenital malformations or rheumatic heart disease is most frequently associated with this class of organisms Similarly infections of the urinary tract with nonhemolytic streptococci may be encountered when anomalies or obstruction of the outflow tract are present The nature of the organism which lodges on the heart valves in endocarditis would appear to be a matter of chance rather than the expression of specific pathogenic properties Although the streptococci involved usually do not belong to one of the recognized groups members of certain serologic groups are also encountered For example group D streptococci which normally inhabit the gastrointestinal tract (enterococci) are often incriminated in endocarditis as well as in urinary tract infection Members of other groups (e g group O) are also occasionally isolated from the bloodstream of patients with endocarditis

Because of the pre eminent importance of group A streptococci in human disease the following sections deal primarily with the characteristics of infections with these organisms

Respiratory Tract

The primary site of invasion of the human body by group A streptococci is through the upper respiratory tract Streptococcal pharyngitis or tonsillitis is by far the most common of all streptococcal infections and provides the focus from which the organisms are disseminated to initiate most other forms of streptococcal disease

Streptococci appear to have a special predilection for the lymphatic system and in the upper respiratory tract the initial localization of the infection is in the lymphoid tissue of the pharynx The infectious process is manifested by swelling and reddening of the tonsils and other pharyngeal lymphoid tissue and in the classic disease is accompanied by the appearance of focal or confluent accumulations of exudate on the affected areas The adjacent mucous membranes are also commonly involved in the inflammatory process These changes cause soreness of the throat which may be quite marked and in addition the infection leads to systemic manifestations such as fever and general toxicity While this represents the typical picture of the full blown disease streptococcal pharyngitis can also occur with only minimal evidence of inflammation and minimal symptoms

Complications of this relatively superficial infection occur by extension either through lymphatic channels or by direct involvement of other areas The cervical lymph nodes at the angle of the jaw which drain the tonsillar area are usually involved to some degree and become swollen and tender In severe cases infection of these nodes may progress to the formation of purulent abscesses Abscesses may also form in the deep peritonsillar tissues (quinsy) and particularly in infants in the retropharyngeal tissues Like many of the other severe manifestations of streptococcal disease peritonsillar and retropharyngeal abscesses are now relatively rare This is true also of Ludwig s angina which represents cellulitis and subsequent abscess formation in the tissues of the neck especially at the base of the tongue and on the floor of the mouth The extensive swelling associated with all three of these conditions often leads to difficulty in swallowing and serious embarrassment of respiration

Streptococcal infections of the pharynx readily extend to the paranasal sinuses through the natural openings Similarly the eustachian tube is frequently involved and leads to acute infections of the middle ear Both the sinusitis and the otitis media which result from these extensions may develop into chronic purulent processes In the case of otitis media the infection can invade the air cells of the mastoid bone causing mas

Attempts have been made to resolve the cellular components of group A streptococci into definable fractions by electrophoretic technics (Hess and Slade 1955) These experiments involve extracts obtained after disintegration of the cells by sonic oscillation or shaking with glass beads The electrophoretic patterns obtained with extracts of various types have been compared but there is still little information on the biologic activity of the several electrophoretic components

RELATIONSHIP BETWEEN STREPTOCOCCI OF GROUP A AND OTHER GROUPS

The basic similarity in the monosaccharide composition of the cell wall carbohydrates of groups A through G has already been mentioned There is in addition evidence for a close biologic relationship between groups A C and G which is based largely on the study of strains of human origin For example it is evident from the discussion of the extracellular products of group A streptococci that the same or similar substances are in most cases also produced by some strains of groups C and G Certain of the enzymes such as streptokinase and deoxyribonuclease may be found in cultures of some other groups but it is only in groups C and G that one finds a total complement of extracellular substances approaching that of group A Further support for the interrelationship comes from studies on the distribution of surface protein antigens Thus R antigen serologically identical or closely related to the group A substance has been found in members of groups C and G streptococci as well as in some of group B (Maxted 1949)

The group specific carbohydrate of group C appears to differ from that of group A primarily in the fact that N acetyl galactosamine rather than N acetyl glucosamine has a terminal position on the side-chains and serves as the major antigenic determinant (Krause and McCarty 1962) The structure of the remainder of the molecule is essentially the same and mutants of group C streptococci have been isolated which produce a carbohydrate lacking the N acetyl galactosamine determinants and possessing the chemical and serologic properties of group A variant carbohydrate (Araujo and Krause, 1963)

Several of the streptococcal groups other than A have been subdivided into serologic types but in no case has a type specific protein antigen been identified which has been clearly shown to have a relationship to virulence comparable with that of M protein Type differentiation in group C streptococci has not been explored intensively, but it appears to depend on surface protein antigens and it is possible that in some instances these may be M like in their biologic properties In the case of other groups in which specific types have been described (groups B D, F and G) the available evidence suggests that the type specific substance is polysaccharide in nature This has been clearly established in the case of group B streptococci which have polysaccharide capsules analogous to those of pneumococci

The various similarities and dissimilarities between hemolytic streptococci do not fall in sufficiently uniform patterns to allow for many broad generalizations On the whole however it seems clear that they are much more closely related to one another than to the numerous nonhemolytic and anaerobic streptococci

HEMOLYTIC STREPTOCOCCAL INFECTIONS IN MAN

Hemolytic streptococci are associated with a wide variety of disease entities in man and in the vast majority of these acute infections the causative organisms belong to group A Streptococci of groups C and G, possibly as a reflection of their biologic similarities to group A are sometimes implicated in similar infections especially those involving the upper respiratory tract These infections with groups C and G streptococci are characteristically mild and usually do not lead to the complications observed in group A infections They are not known to initiate late sequelae such as rheumatic fever or glomerulonephritis Occasionally other groups of streptococci are encountered in association with pathologic processes which are more commonly caused by group A streptococci For example puerperal fever can result from group B streptococcal infection of the post

more commonly associated with scarlet fever than others This may conceivably be refer able to the relative capacity of individual strains to produce erythrogenic toxin in large amounts in vivo but a correlation of this kind has not been demonstrated by labora tory studies

Scarlet fever has been described in asso- ciation with upper respiratory infections with group C streptococci and even in infections with more distantly related organisms the staphylococci In the latter case the staphylo cocci involved are found to produce an erythrogenic toxin with properties like that of the streptococcal toxin However these are relatively rare exceptions and in nearly all cases of the disease group A streptococci are recovered on culture

OTHER ACUTE STREPTOCOCCAL INFECTIONS

While the upper respiratory tract is the principal site of group A streptococcal infec tions these organisms have the capacity to localize and produce infections in many other areas The initiation of infection in these areas may result either from hematogenous spread or from the chance inoculation of susceptible tissues with organisms from the environment The adaptability of streptococci to the in vasion of human tissues is well illustrated by their behavior when introduced directly through the normal skin barrier This can occur in a variety of accidental injuries as in the case of infection of cuts or blisters or in natural portals of entry such as the umbilical cord of the newborn infant The course of events following production of le sions of this type by virulent streptococci in the extremities follows a well defined pattern *The lymphatic vessels are quickly involved* often with minimal evidence of reaction at the site of the local lesion and the occur rence of advancing lymphangitis is visibly manifested by the appearance of red streaks moving up the arm or the leg The draining lymph nodes become swollen and tender but do not significantly check the centripetal spread of the lymphatic infection which con tinues until it reaches the bloodstream and gives rise to septicemia Frequently the progress of this type of infection is so rapid that septicemia and death can occur within 24 to 48 hours of the initial injury Varia tions in virulence of the organism or in host resistance may alter this course of events and one may even encounter localized purulent infections of the skin which spread only in an indolent fashion

Septicemia may develop as a complication of other localized streptococcal infections It is always a most serious manifestation ac companied by high fever and severe toxic symptoms Prior to the discovery of effective chemotherapeutic agents the occurrence of septicemia was always a grave prognostic sign In contrast with this form of blood stream infection which is always associated with some focus that provides a continuing supply of organisms transient bacteremia can occur without giving rise to apparent symp tomatology unless the organisms are able to establish themselves at another site This phenomenon is responsible for hematogenous dissemination of streptococcal infection Thus septic arthritis manifested by the ac cumulation of purulent infected exudate within the joint cavity must be assumed to originate by this process Similarly strepto coccal meningitis sometimes appears in the absence of demonstrable mastoiditis suggest ing that it originates by way of the blood stream rather than by direct contiguity

The classic puerperal fever in its most viru lent form represents a group A streptococcal infection of the postpartum endometrium with subsequent septicemia The evidence in dicates that this endometritis results from direct infection of a highly susceptible tissue At the time that this infection was widely prevalent it was noted that its greatest inci dence coincided with epidemics of scarlet fever and streptococcal sore throat increas *ing the opportunity for dissemination of* streptococci from the respiratory tracts of carriers who came into contact with the pa tient The institution of suitable aseptic tech nics did much to reduce the danger of puer peral fever even as it reduced the occurrence of streptococcal infection of surgical wounds

Erysipelas is a streptococcal skin infection which like scarlet fever was originally thought to be a specific disease until it was demonstrated that the organisms responsible belong to the same serologic types as those causing other streptococcal infections This infection characteristically spreads in all di

toiditis and ultimately osteomyelitis of the surrounding bony structures If invasion of the bone progresses to the meningeal surfaces serious complications such as meningitis or cerebral sinus thrombosis may result

Extension of streptococcal pharyngitis may also occur downward into the lower respiratory tract Here it gives rise to bronchitis and interstitial bronchopneumonia characterized by extensive involvement of the lymphatic vessels Spread of the infection by the lymphatics typical of the streptococcal lymphangitis in other areas follows the flow to the draining lymph nodes but may proceed in a retrograde direction in occluded vessels and reach the pleural surfaces Because of this retrograde extension pleurisy is common in streptococcal pneumonia and leads to the formation of large quantities of serofibrinous pleural exudate

Relative to the great frequency of upper respiratory infections with streptococci pneumonia is a rare event Certain viral infections of the respiratory tract seem to promote the occurrence of this complication when they occur simultaneously with streptococcal infection During World War I for example a large number of cases of streptococcal pneumonia with massive pleural effusion were encountered among military personnel in the course of measles and influenza epidemics

Scarlet Fever

Scarlet fever was recognized as one of the common exanthematous diseases of children for centuries before its streptococcal etiology was discovered Because of this history it is usually considered as a separate disease entity although modern bacteriologic findings indicate that it merely represents streptococcal pharyngitis or tonsillitis with an accompanying rash Thus in a given epidemic of streptococcal disease a single predominant type of group A streptococcus may be recovered from cases of both scarlet fever and streptococcal sore throat

The erythrogenic toxin is responsible for the rash of scarlet fever but the importance of this substance in other toxic manifestations of the disease has not been clearly established As indicated in the discussion of the extracellular products of group A streptococci this substance is only one of several with potentially toxic properties Symptoms of systemic toxicity occur in the case of streptococcal sore throat which are indistinguishable from those of scarlet fever and the degree of this manifestation is more a function of the severity of the disease process than of the presence or the absence of a skin rash Other clinical findings of scarlet fever such as the so called strawberry tongue resulting from the appearance of prominent papillae on an otherwise smooth and diffusely reddened organ also occur in uncomplicated streptococcal pharyngitis The purulent complications of scarlet fever (cervical adenitis sinusitis otitis etc) are identical with those described for streptococcal pharyngitis and the same delayed nonsuppurative sequelae are encountered

The rash of scarlet fever is characterized by diffuse reddening of the skin which may cover most of the body but is frequently most prominent on the trunk The changes induced in the skin result in desquamation during convalescence This is especially evident on the hands and the feet where a thick keratinized layer is present

There are certain anomalies in the occurrence of scarlet fever which are not satisfactorily explained on the basis of susceptibility or immunity to a primary toxin For example, the disease is rarely seen in infants and very young children and infants do not give positive reactions with Dick toxin These findings cannot be correlated with the transfer of passive immunity from the mother and have led to the suggestion that the development of hypersensitivity through prior exposure to erythrogenic toxin is required before this agent can induce the formation of the characteristic rash In any event it is clear that immunity to the toxin is effective in preventing second attacks of the scarlet fever in the vast majority of cases, although it has no effect on the occurrence of subsequent streptococcal infections As noted earlier the occasional occurrence of second attacks of scarlet fever can be explained by the fact that certain strains of group A streptococci produce an erythrogenic toxin which is serologically distinct from that of the majority of strains It is evident also that some epidemics of streptococcal disease are much

majority of recovered patients do not show evidence of chronic kidney damage Further more recurrent attacks of glomerulonephritis are rare

An additional important difference in the pathogenesis of the two diseases has been established recently by the finding that only certain types of group A streptococci appear to be associated with the initiation of glomerulonephritis (Rammelkamp and Weaver 1953) These studies now adequately confirmed show that the great majority of cases are preceded by type 12 streptococcal infections and that the remaining cases are usually attributable to one or two additional types This strongly suggests that some specific property of certain strains of group A streptococci is important in the etiology of glomerulonephritis These findings also serve to explain the rarity of second attacks of the disease as contrasted with the frequent recurrence of rheumatic fever

Erythema nodosum the third representative of this group of diseases is less clearly delineated and only a portion of the cases showing the clinical picture of the disease can be attributed to a preceding streptococcal infection However when this relationship exists it follows the same pattern of delayed appearance after the bacterial infection and can recur following subsequent attacks of streptococcal sore throat The disease is manifested by the occurrence of red extremely tender nodular swellings particularly on the extensor surfaces of the extremities in association with fever and signs of general toxicity Lesions of the same type may be encountered occasionally in rheumatic fever but erythema nodosum is seen more commonly in the absence of other rheumatic stigmata and recovery occurs without residual damage

There is evidence to suggest that these late sequelae of streptococcal infection may represent a severe and exaggerated form of a type of host reaction that is commonly manifested during convalescence Thus during the period following apparent recovery from the acute infections one may encounter recurrent swelling and tenderness of the cervical lymph nodes transient arthralgias transient electrocardiographic changes microscopic hematuria etc The time of appearance of these changes as well as the time of onset of the overt poststreptococcal diseases coincides with the time at which antibody response to streptococcal antigens is reaching its maximum and this has been an important factor in the formulation of the theory that hyper sensitivity reactions are concerned with pathogenesis of the delayed sequelae

IMMUNITY

As noted earlier specific antibodies to most of the extracellular products of group A streptococci are demonstrable in the serum of a large percentage of patients after recovery from streptococcal infections Similarly certain of the surface antigens and cellular components have been shown to induce antibody response (see review in McCarty 1954) Furthermore even though the number of individual streptococcal antigens which have been studied is relatively large it is evident that this represents only a portion of the potential antigens These findings emphasize perhaps more clearly than in the case of any other bacterial infection that the patient with a streptococcal infection is exposed to a wide variety of different antigenic substances during the active disease However there are few instances in which the antibodies produced can be related to immunity to infection Among the several extracellular substances for example only the antibody to the erythrogenic toxin has been shown to have a readily demonstrable effect on a disease manifestation Since the antibodies to other toxins and enzymes usually inhibit their action it is conceivable that they may affect the development of the disease process in a manner that remains undefined

In general immunity to streptococcal infection is type-specific and depends on the production of antibodies to M protein This has been demonstrated both in experimental infections in laboratory animals and in natural infections in man Studies of repeated attacks of streptococcal pharyngitis in a single individual have shown that each episode is associated with a different type of group A streptococcus and that recurrent infections with the same type are extremely rare In this connection it should be noted that effective penicillin therapy can suppress the antibody

rections in the subepidermal tissues from an original focus which may or may not be readily apparent The inflammatory process is manifested by redness and edema and the *advancing elevated margin of the lesion is* clearly demarcated from normal skin Streptococci are usually demonstrable only in the edema fluid from the advancing edge The area of skin involved may be extensive and in severe cases deeper penetration or septicemia can ensue

Streptococci are also involved in the superficial purulent skin lesions of impetigo contagiosa Here they are usually found in association with staphylococci and the lesions assume a *more chronic and indolent* character They begin as individual vesicles which subsequently break with the formation of encrusted purulent lesions

Delayed Sequelae of Streptococcal Infections

This group of diseases includes acute rheumatic fever acute hemorrhagic glomerulonephritis and erythema nodosum They represent an entirely different order of disease phenomena from the various suppurative complications of acute streptococcal disease in which the infecting organisms play so prominent a role The mechanisms involved in the initiation of the delayed sequelae by streptococcal infection have not been clarified but it is evident not only that the clinical findings are unique but also that the nature of the pathologic lesions is distinct from that of the processes in which direct bacterial involvement is evident

Rheumatic fever is the most important and *widespread of the late sequelae* Characteristically this disease is preceded by a typical streptococcal infection of the upper respiratory tract and has its onset after a latent interval which is variable in length with an average of about 3 weeks The nature and the severity of the *symptoms of rheumatic fever* cover a wide range However the most prominent features of the classic disease are fever, migratory polyarthritis and carditis The arthritis is not to be confused with the acute septic arthritis mentioned previously since streptococci are *not demonstrable in* the joint fluid and recovery occurs without residual damage to the joint Involvement of the heart is the most significant aspect of the disease from the point of view of both the severity of the acute illness and the production of permanent damage All layers of the *heart may be affected* and signs of myocarditis and pericarditis are frequently present The basic pathologic finding is a focal inflammatory process characterized by the occurrence of unique myocardial lesions known as Aschoff bodies Involvement of the endocardium can result in deformative scarring of the valves and adjacent structures which leads to chronic rheumatic valvular heart disease

The generalized nature of the rheumatic *process is illustrated* by the variety of other manifestations which may occur in the course of the disease including involvement of the skin and of the central nervous system (chorea) The disease may become subacute or chronic and in extreme cases evidence of rheumatic activity may persist *for years After* recovery from rheumatic fever the patient is highly susceptible to recurrence of the disease following a new streptococcal infection and many attacks can occur in a single individual

There appears to be no strain selectivity among group A streptococci in their ability to initiate rheumatic fever since practically all of the prevalent serologic types have been found to be associated with the disease However only a small percentage of patients with streptococcal sore throat develop this late complication and it is evident that host factors must play a role in the pathogenesis of the disease

Acute hemorrhagic glomerulonephritis re*sembles rheumatic* fever in the occurrence of a latent interval between the streptococcal infection and onset of the disease although in this case the average length of the interval is probably shorter As the name suggests this disease involves primarily the glomerulus *of the kidney and is associated* with the appearance of blood in the urine and general manifestations of kidney disease such as edema and hypertension As might be expected from their common origin rheumatic fever and glomerulonephritis occasionally *occur simultaneously in the same* patient However there is less evidence of permanent damage in glomerulonephritis and the great

majority of recovered patients do not show evidence of chronic kidney damage Furthermore recurrent attacks of glomerulonephritis are rare

An *additional important difference* in the pathogenesis of the two diseases has been established recently by the finding that only certain types of group A streptococci appear to be associated with the initiation of glomerulonephritis (Rammelkamp and Weaver 1953) These studies now adequately confirmed show that the great majority of cases are preceded by type 12 streptococcal infections and that the remaining cases are usually attributable to one or two additional types This strongly suggests that some specific property of certain strains of group A streptococci is important in the etiology of glomerulonephritis These findings also serve to explain the rarity of second attacks of the disease as contrasted with the frequent recurrence of rheumatic fever

Erythema nodosum the third representative of this group of diseases is less clearly delineated and only a portion of the cases showing the clinical picture of the disease can be attributed to a preceding streptococcal infection However when this relationship exists it follows the same pattern of delayed appearance after the bacterial infection and can recur following subsequent attacks of streptococcal sore throat The disease is manifested by the occurrence of red extremely tender nodular swellings particularly on the extensor surfaces of the extremities in association with fever and signs of general toxicity Lesions of the same type may be encountered occasionally in rheumatic fever but erythema nodosum is seen more commonly in the absence of other rheumatic stigmata and recovery occurs without residual damage

There is evidence to suggest that these late sequelae of streptococcal infection may represent a severe and exaggerated form of a type of host reaction that is commonly manifested during convalescence Thus during the period following apparent recovery from the acute infections one may encounter recurrent swelling and tenderness of the cervical lymph nodes transient arthralgias transient electrocardiographic changes microscopic hematuria etc The time of appearance of these changes as well as the time of onset of the overt poststreptococcal diseases coincides with the time at which antibody response to streptococcal antigens is reaching its maximum and this has been an important factor in the formulation of the theory that hypersensitivity reactions are concerned with pathogenesis of the delayed sequelae

IMMUNITY

As noted earlier specific antibodies to most of the extracellular products of group A streptococci are demonstrable in the serum of a large percentage of patients after recovery from streptococcal infections Similarly certain of the surface antigens and cellular components have been shown to induce antibody response (see review in McCarty 1954) Furthermore even though the number of individual streptococcal antigens which have been studied is relatively large it is evident that this represents only a portion of the potential antigens These findings emphasize perhaps more clearly than in the case of any other bacterial infection that the patient with a streptococcal infection is exposed to a wide variety of different antigenic substances during the active disease However there are few instances in which the antibodies produced can be related to immunity to infection Among the several extracellular substances for example only the antibody to the erythrogenic toxin has been shown to have a readily demonstrable effect on a disease manifestation Since the antibodies to other toxins and enzymes usually inhibit their action it is conceivable that they may affect the development of the disease process in a manner that remains undefined

In general immunity to streptococcal infection is type-specific and depends on the production of antibodies to M protein This has been demonstrated both in experimental infections in laboratory animals and in natural infections in man Studies of repeated attacks of streptococcal pharyngitis in a single individual have shown that each episode is associated with a different type of group A streptococcus and that recurrent infections with the same type are extremely rare In this connection it should be noted that effective penicillin therapy can suppress the antibody

response to various streptococcal antigens, including the extracellular products and M protein, and consequently may result in an increased incidence of second infections with a single type Following untreated infection, the great majority of patients develop M antibody which is measurable by the bactericidal technic previously described There is evidence that type specific antibody may persist in detectable amounts for many years and thus provide a basis for prolonged immunity to a given type

Although type specific immunity has been established as a major factor in streptococcal disease certain aspects of the natural history of these infections suggest the possibility of some form of nonspecific resistance or immunity Experiments with laboratory animals have contributed little in this regard In the naturally occurring disease streptococcal infections are most common among school children and there is a progressive decrease in incidence with advancing age Considering the large number of types of group A streptococci which may be prevalent at different times it is difficult to ascribe the relative immunity of adults entirely to type specific immunity However, many factors other than humoral immunity may play a role in this problem and under appropriate conditions of increased exposure as in military establishments the incidence of streptococcal infections in adults can be very high

In addition to a decrease in incidence of streptococcal infections with age there are changes in the characteristic manifestations of the disease that may be related to the immune response For example in infants under 3 years of age the disease is commonly a low grade subacute process which can last several weeks and often does not show the clear cut localizing signs that characterize streptococcal pharyngitis in the older child and adult These changes have been emphasized by Powers and Boisvert (1944) who suggested the term streptococcosis for all streptococcal disease in analogy with the course of events in tuberculosis The development of immunity and hypersensitivity is considered to play a major part in the changing patterns of both diseases There is evidence that the vigorous type of antibody response to a variety of streptococcal antigens in children and adults may be dependent on prior conditioning during streptococcal infections in infancy Thus, it has been found (Rantz *et al*, 1951) that the production of antistreptolysin O is often very feeble in young infants and that even in children from 1 to 6 years of age increased antibody levels are maintained for a shorter period of time than in older children In addition, the appearance of detectable levels of M antibody after infection is usually greatly delayed in comparison with antibodies to the extracellular products This can be explained best by assuming that the latter represent the secondary or anamnestic type of antibody response while the M protein is a new antigen to which the individual has not been exposed previously If this explanation is correct it supports the view that the antistreptolysin O type of response characteristic of the older patient is conditioned by prior exposure to the antigen

During the past several decades there seems to have been a progressive decline in the severity of streptococcal infections This is most evident in the case of readily recognizable manifestations such as scarlet fever This decrease in severity unaccompanied by a comparable decrease in the morbidity rate antedates the introduction of *antibacterial* drugs and it must be assumed that either changes in the virulence of the organism or in the susceptibility of the human population or possibly a combination of both factors are responsible Similar changes in the severity of scarlet fever were reported in past centuries and although the validity of these older observations is uncertain the possibility of recurring cycles of varying disease intensity is suggested The fact that the immunity status of a population can play a key role in the severity of streptococcal disease is indicated by the highly fatal streptococcal epidemics that are seen occasionally in isolated groups not previously exposed to streptococci It is evident that the matter of nonspecific immunity to streptococcal infection requires further study

Immunity in rheumatic fever is no more than a special case of streptococcal *immunity* The same antibodies are formed as in streptococcal infections which do not give rise to this delayed complication However, there

may be a quantitative difference since in a given epidemic of streptococcal disease the mean antibody response of rheumatic fever patients to a variety of streptococcal antigens is greater than in patients with uncomplicated infections In the case of glomerulonephritis the importance of type specific immunity is emphasized As pointed out earlier the low incidence of recurrences of this disease in contrast with rheumatic fever probably depends on the fact that a single type of group A streptococcus is responsible for most of the disease Thus the development of M antibody to this type during the first attack greatly reduces the chance of a recurrence

DIAGNOSIS

Few of the many manifestations of streptococcal disease are sufficiently distinctive to allow for conclusive diagnosis on clinical grounds alone Scarlet fever and erysipelas exemplify the more readily recognizable streptococcal infections and classic attacks can be diagnosed with reasonable accuracy from the signs and symptoms However the findings in streptococcal pharyngitis and tonsillitis are much more variable than they were once thought to be In many cases exudate is absent and the inflammation of the pharynx cannot be distinguished from that caused by a variety of other upper respiratory infections Even when exudate or follicular tonsillitis is present the diagnosis is not certain because of the occurrence of non streptococcal infections which give a similar picture It must be concluded that isolation of the organism by bacteriologic culture is of primary importance in accurate diagnosis

The material for culture is most commonly obtained from the throat or the nasopharynx by the use of a sterile swab It is important to transfer the material promptly to the culture medium without allowing the swab to become dry This is done most conveniently by rolling the swab on the surface of a blood agar plate after which the inoculum is streaked out with a sterile bacteriologic loop In this way an adequate distribution of the material is usually obtained so that isolated colonies appear The nature of the blood used is of importance and sheep blood is recommended because of its property of suppressing the growth of certain hemolytic members of the genus Hemophilus However the zones of hemolysis are not always typical and some workers use both rabbit and sheep blood plates in the initial isolation of streptococci The use of blood of other species (human horse) may lead to difficulties in the recognition of hemolytic colonies and requires special care and experience In order to obtain typical colony formation it is preferable to use fresh blood agar plates or plates that have been sealed to prevent the loss of moisture during refrigeration

After overnight incubation the plates are examined for the presence of hemolytic colonies In the majority of streptococcal infections a large number of characteristic colonies with distinct hemolytic zones will be apparent if a satisfactory culture technic has been employed In some instances however because of the occurrence of strains which show little hemolysis on initial isolation or do not produce streptolysin S the presence of streptococci may not be obvious Experience is required to recognize colonies of these strains although certain technics may assist in identifying them Thus when streaking the culture one may make a stab deep into the agar through the heavily inoculated portion of the plate so that subsurface colonies will form which can show hemolysis as the result of production of streptolysin O Some workers recommend the use of anaerobic culture conditions as a means of increasing the efficiency of isolating streptococci on initial culture

In view of the primary importance of group A streptococci and the possible occurrence of streptococci of other groups in the human *throat further identification of the organism* should be carried out by serologic grouping Since grouping antisera are now available commercially this additional step is feasible in most diagnostic laboratories For this purpose isolation of individual colonies and growth in pure culture in amounts sufficient to prepare extracts containing the group-specific carbohydrate are required Typing of proved group A streptococci has a more limited application and usually is carried out only in connection with special studies

Some confusion may result in attempting to differentiate streptococcal carriers from

patients with acute streptococcal disease by means of cultural studies However, group A streptococci are not often the predominant organism in the throat of carriers, and whenever these organisms are present in large numbers in association with symptoms of respiratory disease the diagnosis of streptococcal infection must be made

The use of cultures is of relatively little value in the diagnosis of rheumatic fever and glomerulonephritis since the initiating streptococcal infection usually has subsided before the onset of these late complications However antibody studies have proved to be of value in establishing the occurrence of a recent streptococcal infection Thus, the titers of antistreptolysin O antistreptokinase and antihyaluronidase are still increasing at the time of onset of most cases of rheumatic fever and in doubtful cases this immunologic information may be of importance in supporting the clinical diagnosis

TREATMENT

Prior to the introduction of the sulfonamide drugs, the methods available for treatment of streptococcal infections were generally unsatisfactory Hemolytic streptococci *proved to be among the most susceptible of* all pathogenic bacteria to the bacteriostatic action of sulfanilamide and the discovery of this drug began a new era in the management of streptococcal disease The effect of the new drugs was most dramatic in the highly fatal forms of infection e g meningitis and septicemia which were seldom treated successfully by older methods The number of effective therapeutic agents has been increased by the subsequent discovery of penicillin and some of the other antibiotic drugs such as the tetracyclines since here again streptococci are among the most susceptible of all bacteria

Penicillin in constrast with the sulfonamides is bactericidal for streptococci and the use of this agent is the treatment of choice in most cases of severe streptococcal disease When penicillin is used in adequate dosage for a sufficient period of time it is possible to eliminate the organisms from the upper respiratory tract so that they are no longer recoverable on culture Sulfonamides, on the other hand, act by retarding the multiplication of streptococci which allows the natural host defenses to control the infection However, viable streptococci usually remain in the respiratory tract and the sulfonamides are not effective in eliminating the carrier state The difference in mode of action of the two drugs is reflected in their effect on antibody formation The antistreptolysin O response of patients treated with sulfonamides is not significantly different from that of the untreated patient while the response of penicillin treated patients is markedly depressed Thus destruction of the organisms appears to reduce the antigenic stimulus

Hemolytic streptococci do not appear to be able to give rise to antibiotic resistant mutants with the ease displayed by staphylococci and certain other organisms Despite the widespread use of penicillin in the general population there has been no significant change in the penicillin sensitivity of organisms isolated from streptococcal infections Even in the laboratory it is difficult to isolate variants of group A streptococci with significant resistance to penicillin Sulfonamide resistant mutants of a few serologic types of group A streptococci became prevalent following a mass prophylaxis experiment with sulfon*amides in military populations during World* War II but subsequently the incidence of these strains has greatly decreased In general it would appear that drug resistance is not a major problem in the treatment of streptococcal disease A more important complication arises from hypersensitivity of the host to the therapeutic agent Reactions of various kinds have been encountered with the sulfonamides, and at the present time there is an increasing incidence of hypersensitivity to penicillin Since penicillin sensitivity may be expressed by an acute anaphylactoid reaction the results of administration of the drug to a sensitive individual can be serious Consequently care must be exercised in the use of penicillin particularly when it is given by parenteral injection

It has been established that the prompt use of penicillin therapy in streptococcal sore throat will greatly reduce the occurrence of rheumatic fever Prevention of rheumatic fever depends on elimination of the organisms and the sulfonamides are totally ineffec

tive for this purpose When the symptoms of rheumatic fever have already developed penicillin therapy is indicated for the destruction of any streptococci remaining in the body but it appears to have little effect on the course of the acute disease However the exquisite sensitivity of group A streptococci to antibiotics has been exploited successfully in preventing recurrence of rheumatic fever in known rheumatic subjects For this purpose either penicillin or sulfonamide is effective and the continuous use of one of these agents in doses below that required for treatment of active disease decreases the risk of acquisition of a streptococcal infection and consequently the risk of recurrence of rheumatic fever

EPIDEMIOLOGY

The incidence of streptococcal infections varies in different geographic areas They are most common in the colder climates and in the north temperate zone reach a peak incidence during the winter and the early spring The apparent rarity of streptococcal infections in tropical and subtropical regions may be due in part to the fact that the disease occurs in an atypical or subclinical form since culture surveys and antibody studies indicate that the incidence of infection is higher than had been supposed on clinical grounds Crowding plays a role in the dissemination of infection The influence of this factor is illustrated by the frequency of the disease in crowded tenements and military barracks

Transmission of streptococcal infections depends primarily on intimate contact between individuals with dissemination of the organisms from the upper respiratory tract Prior to the institution of modern methods for handling and pasteurizing milk milk borne epidemics often resulted from contamination of milk by infected employees Isolated outbreaks due to infected food are still encountered occasionally but the major problem in the spread of streptococcal disease is concerned with the transfer of organisms from the respiratory tract of one individual to another

Viable streptococci are recovered readily from a variety of sources in the immediate environment of individuals who harbor the organism Thus they are found in the dust of the room in blankets on books and other objects handled by the patient These environmental reservoirs were formerly considered to be of great importance in spread of the disease but recent detailed epidemiologic studies in a military installation throw serious doubt on their significance These studies and other aspects of the epidemiology of streptococcal infections are discussed in detail by Rammelkamp (1957) The major risk of acquiring a streptococcal infection at least under the conditions of barracks life seems to be in the proximity to a carrier who is disseminating viable organisms

After spontaneous recovery from streptococcal upper respiratory infection some individuals continue to harbor the infecting organism for long periods of time In these cases streptococci can be recovered repeatedly on culture of the nasopharynx or the throat Even when cultures are negative residual organisms may remain in lymphoid tissue as indicated by the isolation of streptococci from the deep tissues of excised tonsils The potential danger of a carrier depends on a number of factors such as the number of organisms present the biologic state of the organisms and the ease with which they are disseminated into the environment In general the ability to spread infection appears to diminish with the time which the streptococci have resided in the upper respiratory tract This decrease in infectivity is referable to qualitative changes in the organisms as well as to reduction in numbers and it has been found that in many cases streptococci tend to lose their M protein during prolonged residence in the pharyngeal tissues (Rothbard and Watson 1948)

The carrier state is not necessarily dependent on previous clinical infection During epidemic periods of streptococcal disease culture surveys of school and military populations have shown that a large proportion of the population up to one third or more may carry one of the types of group A streptococci involved in the epidemic During the pre epidemic period there is often a progressive rise in the carrier rate which precedes the occurrence of significant numbers of frank streptococcal infections Epidemics can be avoided, or terminated abruptly once they

occur, by the use of mass penicillin pro phylaxis

The Pneumococci

The pneumococcus is a gram positive coccus frequently of lancet shape usually arranged in pairs or short chains The viru lent forms possess an easily demonstrable capsule Pneumococcus is nonmotile and does not form spores It is lysed by bile salts and other surface active agents It is classified into types on the basis of immunologic and chemical differences in the highly polymer ized polysaccharides which compose its cap sule It is an inhabitant of the upper respira tory tract of man and certain animals and causes infection primarily in the respiratory tract and adjacent structures especially pneu monia sinusitis otitis conjunctivitis and meningitis

Synonyms are *Diplococcus pneumoniae* and *Streptococcus pneumoniae*

HISTORY

Pneumococcus was first isolated and cul tured in 1881 by Pasteur in France and in dependently in the same year by Sternberg in New York In both instances saliva of per sons who were not suffering from a respira tory disease was injected into rabbits from whose blood the organisms were subsequently isolated Neither Pasteur nor Sternberg recog nized the relationship of the organism to disease This was demonstrated by the inde pendent studies of Frankel and of Weichsel baum between 1884 and 1886 who showed pneumococcus to be the most frequent cause of lobar pneumonia in man

Classification of pneumococcus into types began in Germany with the work of Neufeld and Handel (1909 and 1910) who observed that strains of pneumococci differ in their immunologic properties Shortly afterward Dochez and Gillespie (1913) in New York subdivided pneumococci into 3 distinct types and a 4th heterogeneous group on the basis of agglutination reactions and protection tests in mice Simultaneously Lister in South Africa reported similar findings Two of the types described by Dochez and Gillespie namely Types I and II have been associated with pneumococcal pneumonia in adults more commonly than any of the other types to gether they were responsible for about one half of all cases during the 20 year period between 1920 and 1940 During the past two decades infection caused by Type II has been very uncommon on the eastern seaboard of the United States in contrast with the earlier experience (Austrian 1959) Infor mation on type incidence in other sections of the country is not available

Type III the 3rd type described by Dochez and Gillespie is carried in the normal human pharynx more commonly than any other sin gle type of pneumococcus and is likewise a frequent cause of pneumonia and other le sions Subsequent study of the heterogeneous group IV of Dochez and Gillespie has re sulted in the recognition of more than 80 distinct pneumococcal types

Pneumococcus was first isolated and cultured in 1881 by Pasteur in France and independently in the same year by Sternberg in New York In both instances saliva of persons who were not suffering from a respiratory disease was injected into rabbits from whose blood the organisms were subsequently isolated Neither Pasteur nor Sternberg recognized the relationship of the organism to disease This was demonstrated by the independent studies of Frankel and of Weichselbaum between 1884 and 1886 who showed pneumococcus to be the most frequent cause of lobar pneumonia in man

Classification of pneumococcus into types began in Germany with the work of Neufeld and Handel (1909 and 1910) who observed that strains of pneumococci differ in their immunologic properties Shortly afterward Dochez and Gillespie (1913) in New York subdivided pneumococci into 3 distinct types and a 4th heterogeneous group on the basis of agglutination reactions and protection tests in mice Simultaneously Lister in South Africa reported similar findings Two of the types described by Dochez and Gillespie namely Types I and II have been associated with pneumococcal pneumonia in adults more commonly than any of the other types together they were responsible for about one half of all cases during the 20 year period between 1920 and 1940 During the past two decades infection caused by Type II has been very uncommon on the eastern seaboard of the United States in contrast with the earlier experience (Austrian 1959) Information on type incidence in other sections of the country is not available

Type III the 3rd type described by Dochez and Gillespie is carried in the normal human pharynx more commonly than any other single type of pneumococcus and is likewise a frequent cause of pneumonia and other lesions Subsequent study of the heterogeneous group IV of Dochez and Gillespie has resulted in the recognition of more than 80 distinct pneumococcal types

The basis for the immunologic classification of pneumococci into types was demon

strated by Dochez and Avery (1917) to reside in the elaboration during growth of so-called specific soluble substances (SSS) which constitute the capsules of the microorganisms Heidelberger and Avery (1923) showed that the specific soluble substances are carbohydrate in nature and to them and Goebel is due the greatest part of our knowledge of the immunologic and chemical properties of these capsular constituents The production of the capsular polysaccharides is essential to the pathogenicity of pneumococcus, and antibodies which protect man or animals against infection are directed against this capsular material

Many of the biologic properties of pneumococcus are similar to those of various species of streptococci especially streptococci of the viridans group It is for this reason that certain taxonomists have included pneumococcus as a species of streptococcus under the name *Streptococcus pneumoniae* though agreement on this designation is not universal The most important properties which distinguish pneumococcus from the green producing streptococci are its predilection in causing pneumonia, its virulence for laboratory animals on primary isolation and its dissolution by bile salts and other surface active agents

MORPHOLOGY

In the sputum the pus and the lungs of patients with pneumonia pneumococcus appears singly in pairs or in short chains of ovoid or lanceolate cocci When in pairs, the adjacent ends of the cocci are generally rounded with the distal ends pointed The appearance in artificial culture medium is similar except that short chains of cocci are seen more commonly especially in young cultures During the active phases of growth pneumococcus is gram positive but as the culture begins to age gram negative forms appear which retain their coccoid shape On continued incubation the gram positive forms gradually disappear and eventually are replaced entirely by gram negative cocci This is followed by further autolytic changes so that finally no formed elements but only gram negative debris can be seen

The process of autolysis can be greatly enhanced by surface active compounds On the addition of whole bile or bile salts such as sodium deoxycholate or taurocholate pneumococcus autolyzes with great rapidity the clearing of a turbid suspension of organisms occurring within a matter of minutes The phenomenon of bile solubility is due to activation of the autolytic enzymes of pneumococcus If the enzymes are first inactivated by heating the suspension of cocci at 65 C for 30 minutes, autolysis no longer takes place either spontaneously or when bile is added The mechanism of activation of the autolytic enzyme system by surface active substances has not been explained, though it seems not unlikely that activation results from alteration or removal from the cells of a normal inhibitor of autolysis

On the surface of solid media such as fresh peptone infusion agar plates to which blood has been added young cultures of the virulent organisms form smooth glistening unpigmented dome shaped colonies which are circular in outline and in general vary from 0 5 to 1 5 mm in diameter Colonies formed by Type III pneumococcus are larger and more mucoid than those produced by other types and commonly attain a diameter of from 2 to 3 mm on blood agar The greater size and more mucoid consistency of the Type III colonies are due to the larger amount of capsular polysaccharide synthesized by this type As the cultures on blood agar age autolytic changes appear The centers of the colonies collapse often leaving a small central papilla with a depressed area intervening between it and the raised outer margin of the colony

Surrounding the colonies on blood agar and becoming more apparent with continued incubation at 37° C there is a zone of alpha hemolysis showing the characteristic greenish brown color

In fluid media encapsulated pneumococci grow diffusely and tend to sediment only when the pH has fallen because of acid production This occurs in media containing relatively large amounts of glucose or other fermentable carbohydrates

NUTRITION

In the older literature pneumococcus is characterized as a fastidious" microorganism indicating difficulties in cultivation and

maintenance in the viable state These difficulties were probably multiple in nature and due not only to partial deficiencies in essential nutrients but also to improper oxidation reduction potential of the medium

The importance of the oxidation reduction potential has been clarified, especially through the studies of Dubos (1929) When peptone meat infusion broth is exposed to the air the medium becomes oxidized Under such circumstances large inocula of pneumococcus must be used to obtain growth The large inoculum is able through its metabolic activity to lower the redox potential sufficiently to permit growth whereas with a small inoculum this may not occur When the medium is reduced by placing it under reduced pressure by heating to drive off dissolved oxygen or better by addition of a reducing agent such as cysteine or thioglycollic acid growth can be initiated from a very small inoculum Media satisfactory for pneumococcal growth can be prepared readily from fresh meat infusion with the addition of any good brand of peptone The pH of the medium should be between 7 2 and 7 4 after sterilization which should be accomplished with a minimum of heating Media made with a fresh meat infusion base are in general more satisfactory than the dehydrated media which are commercially available

The optimum pH for growth of pneumococcus is stated to be 7 8 Excellent growth can be obtained over the range of pH 7 2 to 7 8 but from the practical viewpoint it is probably desirable to use media of pH 7 2 to 7 4 because there is less chance of deleterious alterations occurring on sterilization by heat at lower pH values

All of the nutritional factors required for growth of pneumococcus have not been determined However a partially defined medium has been prepared by Adams and Roe (1945) which supports the growth of many but not all strains This medium is basically that designed by Bernheimer *et al* (1942) for the cultivation of Group A streptococci with the addition of asparagine and choline which have been shown to be essential for growth of most pneumococcal strains tested In addition to an acid hydrolysate of casein supplemented by l cystine and l tryptophane the medium contains the following accessory growth factors biotin nicotinic acid pantothenic acid choline pyridoxine thiamine riboflavin adenine and uracil Of these the first 4 are known to be essential In common with Group A streptococci pneumococcus has been found to require large amounts of glutamine Immediately before inoculation sodium bicarbonate is added to provide CO which is essential for the initiation of growth and the redox potential is lowered by the addition of a reducing agent such as thioglycollic acid Glucose is used as a carbon source since pneumococcus derives almost all of its energy requirements from anaerobic glycolysis Table 1 which is taken from the paper by Adams and Roe lists the components of the partially defined medium and the method of preparation Further work is required to find out if all of the accessory growth factors listed are essential for pneumococcal growth and to determine the amino acid requirements

Defined media such as that described are especially useful for chemical investigations of bacteria for example the preparation of capsular polysaccharides or somatic proteins because all of the constituents of the medium are dialyzable and can be eliminated by this means

For routine cultivation of pneumococcus it is preferable to use complex media such as peptone fresh meat infusion broth to which blood has been added Growth of all strains can be obtained autolysis is less rapid than in the defined medium described and cultures can be stored in the refrigerator for prolonged periods of time The presence of blood is particularly important for storing cultures Presumably this is because the catalase present in the red cells destroys hydrogen peroxide produced by pneumococcus Pneumococcus contains neither catalase nor peroxidase and in consequence H O accumulates in its environment if air is present, in an amount probably great enough to affect the viability of the organisms In any case although blood does not improve the growth of pneumococcus when added to a good medium its presence favors preservation of viability of the organisms on storage

PHYSIOLOGY

As noted above pneumococcus derives most of its energy requirements from the fer

TABLE 1 COMPOSITION AND METHOD OF PREPARATION OF A PARTIALLY DEFINED MEDIUM FOR PNEUMOCOCCUS*

Basal Medium—for 1 liter of medium	
Acid hydrolysate of casein	200 ml of 10% solution
l Cystine	150 mg
l Tryptophane	20 mg
KCl	3 Gm
$Na_2HPO_4 \cdot 12H_2O$	7 5 Gm
$MgSO_4 \cdot 7H_2O$	0 5 Gm
Distilled water to make	900 ml

Adjust pH to 7 5 heat to boiling filter and tube in 9 ml amounts or appropriate multipl Autoclave

Solution 1—vitamin mixture for 12 5 liters	
Biotin	0 015 mg
Nicotinic acid	15 0 mg
Pyridoxine	15 0 mg
Calcium pantothenate	60 0 mg
Thiamine	15 0 mg
Riboflavin	7 0 mg
Adenine sulfate	150 0 mg
Uracil	150 0 mg

Dissolve in 100 ml of distilled water and sterilize by filtration Store in refrigerator

Solution 2—salt mixture for 50 liters	
$FeSO_4 \cdot 7H_2O$	50 mg
$CuSO_4 \cdot 5H_2O$	50 mg
$ZnSO_4 \cdot 7H_2O$	50 mg
$MnCl_2 \cdot 4H_2O$	20 mg
HCl concentrated	1 ml

Dissolve in 100 ml of distilled water and sterilize by boiling

Addition mixture per liter of medium	
Vitamin mixture (solution 1)	8 0 ml
Salt mixture (solution 2)	2 0 ml
Glucose (20% solution)	10 0 ml
Glutamine	200 mg
Asparagine	100 mg
Choline	10 mg
$CaCl_2 \cdot 2H_2O$	10 mg
Distilled water to make	50 ml

Sterilize by filtration and store in refrigerator Add 0 5 ml to each 9 ml of basal medium This addition mixture should not be kept longer than a few weeks since the glutamine is unstable Solutions 1 and 2 appear to keep indefinitely

Bicarbonate—thioglycollate mixture	
Thioglycollic acid	10%

Add 1 ml of thioglycollic acid to 9 ml of sterile distilled water mix well and heat in boiling water bath for 10 minutes

Bicarbonate Weigh 200 mg samples of sodium bicarbonate into test tubes and autoclave

Add 10 ml of sterile distilled water to a test tube containing bicarbonate and dissolve the latter Then add 0 2 ml of 10 per cent thioglycollic acid and mix well immediately Add 0 5 ml of the mixture to each 9 5 ml of medium This bicarbonate thioglycollate mixture is unstable and must be made up and added to the medium just prior to inoculation

* From Adams M H and Roe A S 1945 A partially defined medium for cultivation of pneumococcus J Bact 49 401

mentation of glucose Practically all of the glucose metabolized can be accounted for by the lactic acid which accumulates in the medium during growth The metabolism of pneumococcus is thus essentially anaerobic However it can grow in the presence or the absence of oxygen and hence has been classified as aerobic or facultatively anaerobic Growth is somewhat better under aerobic conditions even though pneumococcus does not possess a complete cytochrome system or catalase Better growth under aerobic conditions apparently is due to the capacity to take up oxygen through a flavin containing enzyme system Under these conditions H_2O_2 is produced by the auto-oxidation of reduced flavoprotein As previously noted H_2O_2 accumulates in the medium because pneumococcus possesses neither catalase nor peroxidase

One of the most important factors limiting the growth of pneumococcus is the lowering of the pH of the medium due mainly to the accumulation of lactic acid although with some strains significant amounts of formic and acetic acid may be produced (Friedemann 1938) Massive growth can be obtained by supplying a large amount of glucose and neutralizing the lactic acid with NaOH as it is formed For the preparation of the capsular polysaccharides neutralization with NaOH should be avoided Even though alkali is added cautiously and with very careful stirring of the culture during addition it has been shown that degradation of the polysaccharides is likely to occur (Heidelberger *et al* 1950)

IDENTIFICATION

Members of the heterogeneous group of gram positive cocci collectively described under the term viridans streptococci are the only bacteria which are commonly confused with pneumococcus However a single test may be used to separate them namely bile solubility Pneumococcus is bile soluble whereas the viridans streptococcus is not This test is very reliable provided that the conditions are proper and appropriate controls are used In general it is advisable to remove the living organisms by centrifugation from the medium in which they are grown especially if it contains blood or other protein materials The organisms should be suspended in isotonic saline adjusted so that the pH is in the neutral range Under these circumstances pneumococci go into solution with great rapidity either at room temperature or at 37° C on the addition of an equal volume of 10 per cent bile Dissolution is faster at 37° C and if the suspension has not cleared within 30 minutes at this temperature it is most unlikely that the microorganism in question is pneumococcus Individual bile salts such as sodium deoxycholate or sodium taurocholate in a concentration of 1 per cent may be substituted for whole bile in carrying out the solubility test

In recent years use has been made of bile containing disks to distinguish pneumococcus from streptococci A bile disk is placed on a blood agar plate on which the culture has been streaked If pneumococcus is present its growth is inhibited in a zone surrounding the disk whereas the growth of streptococci is unaffected

Disks containing optochin (ethylhydrocupreine hydrochloride) can be used in a similar way Growth of pneumococcus is inhibited by optochin but streptococcal growth is not affected unless very high concentrations of the drug are used

The fermentation of inulin has been used as a differential test to distinguish pneumococci from streptococci While it is true that inulin fermentation is a property of pneumococcus it is not a reliable test when used by itself since certain streptococci especially those of the *salivarius* group share this capacity

Another property which is of great use in identifying pneumococcus is its virulence for mice on inoculation Streptococci of the viridans group are avirulent for mice whereas most strains of pneumococci are highly virulent even on primary isolation However there are important exceptions since certain commonly encountered pneumococcal types for example Type XIV are of low mouse virulence

VARIATION

On cultivating encapsulated pneumococci in nutrient broth to which antipolysaccharide

* From Adams M H and Roe A S 1945 A partially defined medium for cultivation of pneumococcus J Bact 49 401

the culture medium under appropriate environmental conditions is taken up by the growing cells incorporated into their genetic structure replicated and transmitted to the descendants Therefore transformations in pneumococci have great biologic significance because it was by these reactions that it was demonstrated originally that DNA possesses genetic specificity and a method was provided for studying the characteristics of the genetically active material

DNA extracted from pneumococci or other cells is not a single molecular species but rather a mixture of many deoxyribonucleic acids which differ from one another both in their content of purine and pyrimidine bases and their sequence in the nucleotide chains Depolymerization effected by enzymatic chemical or physical means destroys the specificity of DNA as evidenced by the loss of its ability to cause genetic transformation

The mechanisms which enable bacterial cells to take up free DNA from the environment and incorporate it into their genetic constitution is unknown The long threadlike molecules with molecular weights estimated by different investigators to be from 1 000 000 to 16 000 000 are transported across the cell wall and the cytoplasmic membrane and having gained access to the interior of the cell are incorporated into the nuclear apparatus by a process which appears to be analogous to crossing over in genetic exchanges in higher species

The usefulness of transformation reactions in genetic studies has been greatly extended by the discovery of additional hereditary characteristics of pneumococci and other bacterial species which can be altered by them The demonstration by Hotchkiss (1951) that drug resistance can be transferred to sensitive cells by DNA from resistant mutants has provided a series of genetic markers that permit quantitative studies to be carried out with relative ease (Hotchkiss 1957) Other pneumococcal transformations include alterations in the quantity of SSS produced changes in the serologic type of M proteins capacity to produce an adaptive enzyme mannitol phosphate dehydrogenase changes in R colonial morphology It has also been demonstrated (Bracco *et al* 1957) using streptomycin resistance and resistance to optochin (ethylhydrocupreine) as genetic markers that transformations mediated by the respective DNA s can take place reciprocally between pneumococci and distantly related streptococci The efficiency of interspecies transformation is less than the intraspecies reaction presumably because of less accurate fit of heterologous DNA in the receptor choromosome (Krauss and MacLeod 1963)

Until recently genetic transformations have been observed only under artificial conditions in the mouse or in the test tube However the experiments of Ottolenghi and Hotchkiss (1962) show that pneumococcal cultures release genetically active DNA during growth and that recombinants can be recovered from mixed growing cultures in the test tube In addition it has been demonstrated (Ottolenghi and MacLeod 1963) that genetic exchange can occur between two genetically distinguishable populations of pneumococcus growing together in the same living host the mouse These studies support strongly the idea that genetic exchange by way of transformation is a natural mechanism of recombination

ANTIGENIC STRUCTURE

Pneumococcus can be divided into 75 or more types on the basis of differences in the capsules which surround the cells The capsules are composed of highly polymerized polysaccharides which are immunologically distinct for each type Extensive studies carried out especially by Heidelberger Goebel Avery and by Stacey and his associates have provided a chemical basis for the immunologic specificity of the capsular polysaccharides of a number of types Table 2 shows certain of the chemical properties of polysaccharides of Types I II III VIII XIV and XVIII

It has been repeatedly noted that the capsular polysaccharides of pneumococci are antigenic in certain species such as man and mouse whereas in other species such as rabbit they are not antigenic but behave rather as haptenes However antipolysaccharide antibodies in very high titer can be prepared readily in rabbits by injecting them with

antibodies have been added after a few serial transfers many of the cocci will be found to be devoid of capsules (Stryker 1916) For example when pneumococcus Type I is grown in the presence of Type I antipneumococcal serum encapsulated Type I pneumococci disappear and are replaced by non encapsulated forms With loss of the capsule the organisms lose type specificity and virtually all of their pathogenicity

On the surface of an agar medium encapsulated pneumococci form characteristic smooth glistening colonies The pneumococci composing the smooth colonies are referred to as *mucoid smooth* or *S* organisms With disappearance of the encapsulated forms such as occurs on cultivation in homologous antiserum the colonies formed on agar lose their glistening appearance and tend to have a finely granular or roughened surface The organisms composing these colonies are spoken of as *rough* or *R*

A third form characterized by colonies with a markedly roughened surface has been described by Dawson (1934) to appear following prolonged incubation of cultures planted on the surface of agar plates Whether grown in fluid or on solid media the organisms of such strains are arranged in chains that may contain several hundred cocci In strains of *viridans* streptococci where colonies having a very rough surface are commonly seen, the cocci also occur in chains of great length The markedly roughened surface seems to be caused in both cases by the coiling and the piling up of the long coccal chains

It has been customary in the past to speak of anti S serum as "causing reversion from S to R thereby inferring that anti S serum in some way depresses capsular synthesis and that anti R serum stimulates it This is an incorrect view Any pneumococcal culture although superficially homogeneous contains a large number of variants and S cultures throw off R mutants at a fairly constant rate It has been shown experimentally that if a mixture of S and R cells is inoculated into broth containing anti S serum R cells have a selective advantage over S and conversely when such a mixture is grown in anti R serum S organisms have a selective advantage over R forms

When certain cultures of R pneumococci are grown in broth containing anti R serum or when the R culture is inoculated into mice the R pneumococci disappear and are replaced by S pneumococci of the same serologic type as that from which the R strain was derived by mutation and selection With some R cultures this does not occur R cultures which revert" to the S form either contain S organisms in numbers so small that they are undetectable unless they are cultivated in a selective environment or else back mutation from R to S has occurred

The enhancement of virulence which occurs upon repeated animal passage is due to a similar process of selection The less virulent forms are destroyed by the host the more virulent are able to survive and thus are specifically selected Selection of drug resistant variants or mutants by cultivating the organisms in increasing concentrations of a particular drug may also be cited as another example of the same process

Variation in pneumococcus can also be studied by means of *transformation reactions* As shown originally by Griffith (1928) pneumococcus of one specific type can be transformed to another specific type by way of the R variant In his original experiments Griffith obtained R cells from a culture of pneumococcus Type II by cultivation in Type II antiserum Then the living R cells derived from Type II were subcutaneously inoculated into mice along with large numbers of heat killed Type III S cells On death of the mice cultures of the heart blood showed the presence of living Type III S cells In other words R cells derived from a strain that originally synthesized Type II capsular polysaccharide had been transformed so that they produced the Type III capsule This alteration in polysaccharide synthesis resulted from a permanent genetic change in the recipient cells

Subsequently it was shown by Avery MacLeod and McCarty (1944) that type transformation can be effected by purified preparations of highly polymerized deoxyribonucleic acids (DNA) DNA from S cells of a particular type when applied to R cells derived from another type cause the latter to synthesize capsular polysaccharide of the type from which the DNA was prepared. Exogenous DNA which has been added to

whole encapsulated pneumococcal cells Recent studies show that the isolated polysaccharides behave not as haptenes in rabbits but as weak primary antigens if injected in appropriate small doses (2 to 20 mcg) Increase in dosage obliterates the immune response in rabbits as it does in the case of the mouse in which species also the effective antigenic dose is critically small (0 2 to 5 0 mcg) Larger doses of polysaccharide result in a state called immunologic paralysis by Felton and Ottinger who first described the phenomenon in the mouse (1942) Paralysis or immunologic unresponsiveness is specific for the polysaccharide injected and does not affect demonstrably the response to unrelated antigens Its mechanism is not yet understood

In both mouse and rabbit the isolated capsular polysaccharides are only weakly antigenic as shown by the very low antibody titers resulting from primary immunization as well as the inability to yield an anamnestic response when injected a second time The ease with which immunologic unresponsiveness can be induced in mouse and rabbit by moderate increases in the dose of polysaccharides probably is related to their low order of antigenicity in these two animal species In rabbits that have developed antipolysaccharide antibodies in high titer following hyperimmunization with intact living or killed pneumococcal cells immunologic paralysis does not occur when large doses of homologous polysaccharide are injected On the contrary such previously immunized rabbits develop a brisk secondary immune response

The somatic portion of the cells although antigenically similar in all types is not identical Antisera prepared against R pneumococci derived from one type agglutinate homologous R organisms to higher titer than heterologous R cells This is due in part to the presence of prolaminelike M proteins which are antigenically dissimilar in pneumococci of different capsular types and in the R organisms derived therefrom (Austrian and MacLeod 1949) In nature cells of a particular capsular type commonly possess an M protein characteristic for that type However capsular polysaccharide and M protein can vary independently of one another as shown particularly by transformation reactions Pneumococcal M proteins have chemical properties similar to M proteins of Group A streptococci but are immunologically distinct

As in β hemolytic streptococci the somatic portion of pneumococcus contains a C or cellular carbohydrate described by Tillett Goebel and Avery (1930) which is immunologically as characteristic of pneumococcus as a species as are the C carbohydrates of the Lancefield groups of streptococci However the C carbohydrate of pneumococcus has not been used as a means of classifying pneumococci

Goebel and Adams (1943) showed that the C carbohydrate forms a portion of the Forsmann (heterophile) antigen of pneumococcus Recent studies of Liu and Gotschlich (1963) have resulted in the identification of the components making up about 80 per cent of the weight of C polysaccharide There are 4 major amino acids (lysine serine glutamic acid and alanine) and 4 amino sugars (D glucosamine D galactosamine 6 phosphate muramic acid and muramic acid phosphate) Almost 35 per cent of the total weight of the polysaccharide is accounted for by D galactosamine 6 phosphate This sugar has not been found previously in bacterial cell walls

Tillett (1928) demonstrated that rabbits immunized with heat killed R pneumococci develop resistance to infection with virulent encapsulated pneumococci of Types I II and III Subsequently Dubos (1938) extracted a soluble antigen from pneumococcal cells which caused the production in rabbits of antibodies capable of protecting mice against infection with both homologous and heterologous types The nature of the antigen responsible for the broad immunity studied by Tillett and by Dubos is unknown although there is evidence that the C polysaccharide may be involved (Enders Wu and Shaffer 1936) Antibodies to M protein are not protective However it is worth emphasizing that non type specific resistance to infection obtained by the methods described above is slight when compared with the high degree of immunity afforded by type specific antibodies and probably plays a minor part in protection against pneumococcal infection

TABLE 2 PROPERTIES OF THE SPECIFIC CAPSULAR POLYSACCHARIDES OF SIX PNEUMOCOCCAL TYPES

TYPE	$[\alpha]_D$	ACID EQUIVALENT	MOLECULAR WEIGHT	N	REDUCING POWER ON HYDROLYSIS AS GLUCOSE	CONSTITUENTS IDENTIFIED	COMMENT
				per cent	per cent		
I[1]	+265 to +277	650	171 000	4 6	30	Galacturonic acid (30%) N acetyl glucosamine acetic acid

tions to this generalization because certain types of which XIV is a good example have a low order of virulence for mice and it is not enhanced on mouse passage Despite its low mouse virulence Type XIV is one of the common causes of pneumococcal pneumonia in children

Similar observations have been made in the rabbit with pneumococcus Type III which although highly virulent for man and mouse is almost avirulent for the rabbit However an occasional strain of Type III has been described which possesses pathogenic properties for rabbits A satisfactory explanation for the difference in virulence of these strains of pneumococcus Type III has not been found

Both dogs and monkeys have been used extensively for the study of pneumococcal lobar pneumonia produced by experimental inoculation by the intratracheal route and under appropriate conditions both are highly susceptible Felines are relatively insusceptible to experimental infection and birds are especially resistant

It is apparent from the observations on pathogenicity described above that the data obtained from studies of one animal species cannot be transferred to another

FACTORS INVOLVED IN PATHOGENICITY OF PNEUMOCOCCUS

Pneumococcus is a good illustration of a bacterial species that produces disease apparently solely through invasive properties in other words because of the capacity to invade and multiply in living tissues without evidence that soluble toxins in the usual sense play a part *Cl botulinum* at the other end of the scale exerts its pathogenicity entirely through a potent exotoxin which is produced outside the body and causes disease on absorption through the gut *Cl botulinum* has no invasive capacity whatsoever Between these two extremes of purely invasive and purely toxigenic pathogens are many species that possess both capacities in varying degrees

The search for a toxin produced by pneumococcus which can account for its disease producing capacity has been unsuccessful It is true that two toxic principles have been identified but since neither of them is liberated in detectable amount except on autolysis of the bacterial cells it is doubtful that either plays a significant part in pneumococcal pathogenicity

Pneumolysin an oxygen labile or O hemolysin is liberated from pneumococcus especially on autolysis (Cole 1914) It is related serologically to the O hemolysins produced by hemolytic streptococci *Cl tetani* and *Cl welchii* as shown by Todd (1934) However it should be noted that hemolysis is never a feature of even overwhelming pneumococcal infection and also that in the case of the 3 toxigenic species noted above which produce similar O hemolysins it has not been proved that these substances play a significant part in disease caused by the respective species

Under conditions of autolysis there is also liberated from pneumococcus a purpura producing principle whose effect can be demonstrated both in the skin and the internal organs of experimental animals injected with sterile pneumococcal autolysates Once again however purpura or other hemorrhagic incidents are not seen except in the rarest instances in pneumococcal infection whether in man or other animals so that the purpura producing principle would appear to have little significance in the pathogenicity of pneumococci

So far as we know at present, pneumococci produce disease and death solely through their capacity to multiply in the tissues However it is not improbable that a toxin is produced in the tissues which differs in nature from any previously studied and that its demonstration requires new methods

Another possible mechanism whereby such a rapidly growing pathogen might produce tissue damage is through the production of local or general acute deficiencies in one or more essential metabolites whether vitamins amino acids purines or constituents of other cell components The demands of bacterial cells having a generation time of from 20 to 30 minutes on available supplies of essential metabolites in the animal body must be great indeed and conceivably the microorganisms might compete for limited supplies of such materials on a more favorable basis than the

TABLE 3 DISTRIBUTION OF PNEUMOCOCCAL TYPES IN ADULTS WITH LOBAR PNEUMONIA

PNEUMOCOCCAL TYPE	NUMBER OF CASES	PER CENT OF TOTAL
I	1 063	28 6
II	425	11 4
III	*500*	*13 5*
IV	131	3 5
V	298	8 0
VI	66	1 8
VII	240	6 5
VIII	287	7 7
Total I VIII	*3 010*	*81 0*
All other types	703	19 0
	3 713	100 0

DISTRIBUTION

Pneumococcus has a world wide distribution It is a normal inhabitant of the nasopharynx of man under all climatic conditions In many parts of the world Types I and II have been reported as the most frequent causes of human disease although in normal people other types are carried more commonly in the pharynx Among other animal species, guinea pigs, monkeys and rats are the only ones that are known to harbor pneumococci commonly These species have little or no importance as reservoirs of pneumococci so far as human disease is concerned However epizootics of pneumococcal pneumonia occur among monkeys in captivity and in the guinea pig pneumococcus Type XIX causes one of the most frequent and fatal epizootic diseases of this species None of the other types is of importance in causing disease in guinea pigs though they may become carriers if other types are experimentally implanted in the nosapharynx In rats severe epizootics have been caused by pneumococcus Type II (Mirick *et al* 1950)

PATHOGENICITY AND HOST RANGE

Infections in man can be caused by any of the more than 75 serologic types of *pneumococcus* However, of this large number of types a few account for most human disease Types I II and III cause approximately one half of all the cases of lobar pneumonia in adults in different parts of the world (Heffron, 1939), with 8 types causing about 75 to 80 per cent of the total number of infections Table 3 which is taken from the summaries of Heffron shows the incidence of lobar pneumonia caused by various types in 3 large cities in the north eastern United States

Following the advent of chemotherapy for pneumococcal infections in the latter half of the 1930s typing of pneumococci from patients with pneumonia was abandoned in most parts of the world because the effectiveness of the new drugs did not appear to be related to the immunologic type causing disease Therefore it is not known whether the type distribution is the same now as it was before antimicrobial drugs were introduced In this respect the data collected by Austrian (1959) on pneumococcal infections in New York City between 1952 and 1957 are of considerable interest In Austrian s series of 1,322 adult patients, pnenmococcus Type II was found only 7 times an incidence of about 0 5 per cent whereas in series of cases collected before 1935, Type II accounted for as much as 11 per cent of adult infections

It should be noted that the figures given in Table 3 are for cases of pneumonia having anatomically a lobar distribution Pneumococci are also the most frequent causative agents of bronchopneumonia

In children below the age of 12 the distribution of pneumococcal types in lobar pneumonia differs from that in adults with Types XIV I VI V VII and XIX *in that order* causing more than half the cases (Heffron) It is of interest that the capsular polysaccharide of Type XIV is immunologically related to blood group A substance (Beeson and Goebel 1939)

Among laboratory animals the mouse is the most susceptible species although rats and rabbits are also highly susceptible to experimental inoculation The virulence of most types for mice can be enhanced by repeated passage due to the selection by this means of the most virulent mutants from a mixed population of cells With many types as few as 1 to 5 cocci inoculated intraperitoneally into mice will cause death within 48 hours However there are important excep

tions to this generalization because certain types of which XIV is a good example have a low order of virulence for mice and it is not enhanced on mouse passage Despite its low mouse virulence Type XIV is one of the common causes of pneumococcal pneumonia in children

Similar observations have been made in the rabbit with pneumococcus Type III which although highly virulent for man and mouse is almost avirulent for the rabbit However an occasional strain of Type III has been described which possesses pathogenic properties for rabbits A satisfactory explanation for the difference in virulence of these strains of pneumococcus Type III has not been found

Both dogs and monkeys have been used extensively for the study of pneumococcal lobar pneumonia produced by experimental inoculation by the intratracheal route and under appropriate conditions both are highly susceptible Felines are relatively insusceptible to experimental infection and birds are especially resistant.

It is apparent from the observations on pathogenicity described above that the data obtained from studies of one animal species cannot be transferred to another

FACTORS INVOLVED IN PATHOGENICITY OF PNEUMOCOCCUS

Pneumococcus is a good illustration of a bacterial species that produces disease apparently solely through invasive properties in other words because of the capacity to invade and multiply in living tissues without evidence that soluble toxins in the usual sense play a part *Cl botulinum* at the other end of the scale exerts its pathogenicity entirely through a potent exotoxin which is produced outside the body and causes disease on absorption through the gut *Cl botulinum* has no invasive capacity whatsoever Between these two extremes of "purely" invasive and purely toxigenic pathogens are many species that possess both capacities in varying degrees

The search for a toxin produced by pneumococcus which can account for its disease producing capacity has been unsuccessful It is true that two "toxic principles have been identified but since neither of them is liberated in detectable amount except on autolysis of the bacterial cells it is doubtful that either plays a significant part in pneumococcal pathogenicity

Pneumolysin an oxygen labile or O hemolysin is liberated from pneumococcus especially on autolysis (Cole 1914) It is related serologically to the O hemolysins produced by hemolytic streptococci *Cl tetani* and *Cl welchii* as shown by Todd (1934) However it should be noted that hemolysis is never a feature of even overwhelming pneumococcal infection and also that in the case of the 3 toxigenic species noted above which produce similar O hemolysins it has not been proved that these substances play a significant part in disease caused by the respective species

Under conditions of autolysis there is also liberated from pneumococcus a purpura producing principle whose effect can be demonstrated both in the skin and the internal organs of experimental animals injected with sterile pneumococcal autolysates Once again however purpura or other hemorrhagic incidents are not seen except in the rarest instances in pneumococcal infection whether in man or other animals so that the purpura producing principle would appear to have little significance in the pathogenicity of pneumococci.

So far as we know at present, pneumococci produce disease and death solely through their capacity to multiply in the tissues However it is not improbable that a toxin is produced in the tissues which differs in nature from any previously studied and that its demonstration requires new methods

Another possible mechanism whereby such a rapidly growing pathogen might produce tissue damage is through the production of local or general acute deficiencies in one or more essential metabolites whether vitamins amino acids purines or constituents of other cell components The demands of bacterial cells having a generation time of from 20 to 30 minutes on available supplies of essential metabolites in the animal body must be great indeed and conceivably the microorganisms might compete for limited supplies of such materials on a more favorable basis than the

cells of the host with a resulting acute deficiency for the host cells Other means by which a primarily invasive organism such as pneumococcus causes tissue damage might be suggested but would serve only to emphasize our state of ignorance

Whatever may be the ultimate means by which pneumococcus produces damage to tissues a fact of great significance is that most of the pathogenic power of this species is exerted through possession of a nontoxic surface component—the pneumococcal capsule All virulent strains of pneumococcus possess a capsule which forms a protective mantle about the cells The sole function of the pneumococcal capsule appears to be to *delay or prevent ingestion of pneumococci by* the phagocytic cells of the body The free isolated polysaccharides which compose the capsules in the different types are nontoxic on injection in even very large doses Evidence of the role of the capsule in pathogenicity has been obtained in a variety of ways a number of which will be described

Upon immunization of animals by injecting them with killed encapsulated pneumococci, antibodies are formed which are able to protect other animals infected experimentally with the same type For example a serum prepared by immunizing rabbits with pneumococcus Type I protects against experimental infection with living Type I pneumococci but will not protect against infection with Type II pneumococcus In other words the protective antibodies are type specific

The capsular polysaccharides of several types of pneumococcus have been prepared in relatively pure form as previously noted It has been shown that the protective capacity of a serum depends on the amount of antibody present which is capable of reacting with the capsular polysaccharides By the addition of an appropriate amount of purified specific capsular polysaccharide to a highly protective serum all of the anticapsular antibodies can be precipitated and removed A serum absorbed in this way loses its protective power *Anticapsular* antibodies can also be absorbed from a serum by permitting it to react with whole encapsulated pneumococcal cells and here again the protective power is removed at the same time However one cannot conclude from the results of absorption with whole bacterial cells that it is the anticapsular antibodies that are of importance in protecting against infection since other antibodies reacting with other components of the pneumococcal cell may be removed simultaneously On the other hand absorption of serum with purified capsular polysaccharides shows unequivocally that it is the *antibody to this material that is of importance* in protection against infection and at the same time demonstrates the importance of the capsule in the pathogenicity of the organism

Loss of the capsule from R cells which has resulted because of mutation deprives the cells of most of their virulence although *not all With fully virulent encapsulated* strains a dilution of broth culture containing from 1 to 5 viable organisms (1×10^{-8} ml of culture) will kill mice following intraperitoneal injection With R organisms selected from the same strain by growing it in anti S serum 0 5 to 1 0 ml of culture is necessary to cause death or approximately *100 000 000 to 200,000 000 living R organisms* Therefore loss of the capsule has decreased virulence by a factor of roughly 100 000 000 In mice in the case of Types II III and VII virulence is related to the *quantity* of SSS formed by different strains of the same type (MacLeod and Krauss 1950) For example strains of Type II that produce *small amounts of SSS II are less virulent for* mice than strains that form larger amounts

The quantity of SSS synthesized by strains of pneumococci is under genetic control This *can be shown by study of spontaneous* mutants which have different synthetic capacities for a particular polysaccharide and also by genetic transformation reactions carried *out with DNA extracted from* them In the final analysis therefore the virulence factor for a pneumococcal strain can be considered as the gene that controls the amount of capsular polysaccharide synthesized per cell The gene concerned may be expected to vary from one mutated strain to another within a given type as well as from one *type to another* because of the complex nature of the capsular polysaccharides and because of differences in chemical composition among the various types Alteration in the amount or activity of one out of a number of enzymes involved in polysaccharide syn-

thesis may cause diminished polysaccharide formation and result in decreased virulence

The antiphagocytic property of the pneumococcal capsule can be demonstrated in vitro by mixing R and S pneumococci respectively with heparinized normal human blood Phagocytosis of R cells takes place rapidly whereas the leukocytes have a limited capacity to phagocytose the S forms However if a small amount of type specific antiserum is added the S cells are taken up rapidly by the leukocytes The combination of specific antibody with the capsular polysaccharide removes its antiphagocytic property The antiphagocytic action of the capsule appears to be mechanical and not to be caused by a toxic effect on the leukocytes The detailed studies of Wood and his co workers (see review by Wood 1951 52) indicate that when phagocytosis experiments are carried out on smooth surfaces such as glass or wax, encapsulated pneumococci are pushed about by the leukocytes which have difficulty in embracing the organisms within the pseudopodia because the pneumococci slide away over the smooth surface On the other hand on a roughened surface such as blotting paper filter paper fibrin films or fixed sections of lung the leukocytes take up encapsulated pneumococci fairly readily even in the absence of specific antibody because the bacteria can be pinned against obstructions on the roughened surface and then enclosed in the pseudopodic extensions Intracellular digestion ensues Wood has shown that the nature of the surface influences phagocytosis in vivo also

If antibody is added to the mixture of encapsulated pneumococci and phagocytes the nature of the surface on which the experiment is carried out makes little difference The combination of antibody with the capsule appears to make the pneumococci sticky since now they adhere to the leukocytes and are readily ingested

From the foregoing observations it should be apparent that the presence of type specific antibody is not a prerequisite for phagocytosis of encapsulated pneumococci In the absence of antibody phagocytosis is relatively slow but it is enhanced enormously when antibody is added

The studies of Dubos and Avery on an enzyme which specifically digests the capsular polysaccharide of pneumococcus Type III both when the polysaccharide is in the isolated purified state and when it is present on the surface of the living virulent cells provide further evidence for the importance of the capsule in pathogenicity of pneumococci (Dubos 1939 1940) From the soil of a cranberry bog an aerobic sporulating bacillus was isolated which when grown in a medium containing Type III polysaccharide as the sole carbon source is induced to form an enzyme that has the capacity to hydrolyze specifically Type III capsular polysaccharide but none of the other pneumococcal polysaccharides In the test tube the Type III enzyme digests and removes the capsule from either dead or living Type III pneumococci moreover the enzyme when injected as long as 18 hours after the experimental infection of mice rabbits or monkeys with pneumococcus Type III prevents the death of the animals The sole action of the S III enzyme is to remove the pneumococcal capsule by digesting it with the result that the decapsulated bacteria become highly susceptible to phagocytosis It should be emphasized that digestion of the Type III capsule from the living organisms in vitro in no way affects their viability although as long as active enzyme is present, the capsular material is digested as rapidly as it is produced However when transferred to fresh medium lacking the S-III enzyme the pneumococci again produce their capsules normally

A considerable body of evidence has been accumulated therefore which emphasizes the importance of the pneumococcal capsule in pathogenicity On the other hand the part played by somatic factors has received little attention though there is evidence of their significance One of the most clear-cut illustrations of the influence of somatic factors is in the case of two well known laboratory strains of pneumococcus Type III known as A66 and SV III Strain SV III is highly virulent for rabbits whereas A66 has very little virulence even on repeated animal passage The capsular polysaccharide is immunologically identical in both strains Moreover if the capsule is switched from A66 to SV III and vice versa, by means of transformation reactions no change in virulence occurs (Shaffer Enders and Wu 1936) In other words the difference in virulence of

these strains appears to depend on the somatic portion of the cells

Pneumococcus may be of low virulence for a species because of the nature of the capsule Type XIV, for example is avirulent for the mouse on this basis R pneumococci derived from avirulent Type XIV pneumococcus become highly virulent in the mouse when transformed to pneumococcus Type II similarly when virulent Type II pneumococci are transformed to Type XIV by way of the R variant, the newly constituted Type XIV strain is as avirulent for the mouse as naturally occurring Type XIV pneumococci (MacLeod and McCarty 1942)

PATHOGENESIS OF PNEUMOCOCCAL INFECTION

Pneumococcal pneumonia is rarely a primary infection but usually follows damage to the respiratory tract caused by some unrelated agent, whether viral or chemical In most instances pneumonia is preceded by an upper respiratory infection such as common cold or influenza Therefore pneumococcal pneumonia may be classed as a complex infection This relationship to viral infections probably explains why pneumococcal pneumonia is commonest during the cold months of the year in northern latitudes, since common colds and influenza occur with greatest frequency at these times It is unlikely that the virulence of pneumococci for man varies with the seasons

It is apparent from the relation of pneumococcal pneumonia to viral infection that the normal respiratory mucosa must possess great natural resistance to pneumococcus especially when it is recalled that between 40 and 70 per cent of all normal humans are carriers of pneumococci many types of which are potentially virulent The factors normally involved in protection of the respiratory mucous membrane have not been defined and we are also ignorant of the nature of the predisposing injury caused by viruses or chemical irritants such as gases though it seems likely that actual destruction of the superficial cell layers may be important in permitting invasion of underlying tissues Epidemiologic evidence indicates that the possession of type specific antibody not only protects man against infection under natural conditions but also renders him less likely to become a carrier of pneumococci of homologous type (MacLeod *et al*, 1945) However, it is reasonably certain that, in the main normal resistance to pneumococcal pneumonia does not depend on the possession of antibodies reactive with the many types with which one comes in contact but rather on other factors including whether one happens to be a carrier of a highly pathogenic type such as Type I or II

In the healthy adult pneumococcal pneumonia characteristically involves one or more lobes or a discrete portion of them, leaving the remaining bronchopulmonary system relatively uninvolved In infants young children and the aged the lesions more commonly follow a bronchial distribution without the localized character of lobar pneumonia.

Experimental pneumococcal pneumonia has been studied in the monkey by Blake and Cecil (1920) and in the dog by Robertson and others (see Terrell *et al* 1933) In both species pneumonia can be produced successfully by administering a narcotic such as morphine to depress respiration and the cough reflex and then introducing virulent pneumococci into the trachea or directly into a portion of a pulmonary lobe by means of a fine catheter In the dog an important factor is the production of atelectasis in the portion of the lobe infected and it seems likely that atelectasis may be important also in the etiology of lobar pneumonia in man Increased bronchial secretions and edema occurring during viral infections of the upper respiratory tract may play a significant part through plugging of bronchioles and the production of areas of atelectasis In addition, the tendency for secretions to pool in the most dependent portions may explain in part why the lower pulmonary lobes are most frequently involved

PATHOLOGIC AND CLINICAL PICTURE

The lesion in the lung consists essentially of marked edema of the alveolar walls with an outpouring into the alveoli of fibrinous exudate containing large numbers of red blood cells and polymorphonuclear leuko

cytes Therefore the affected lung becomes consolidated The overlying pleura is in volved early with a serous pleural effusion as a common incident Pneumococci in large numbers can be seen throughout the inflamed area but despite their presence both in the alveoli and the alveolar septa necrosis does not take place The absence of necrosis of the alveolar septa explains why upon re covery from the disease the lung is able to return to its original state

Sputum which is usually coughed up throughout the disease is characteristically bloody or rusty the red cells being intimately mixed with the other components Large numbers of pneumococci are usually present and can be identified quickly by immunologic methods especially the Neufeld quellung or capsular swelling reaction

The onset of acute lobar pneumonia is characteristically sudden often with the oc currence of a chill and sharp pleural pain Recovery of untreated cases frequently occurs likewise with dramatic suddenness—the so-called pneumonic crisis which gen erally occurs within 5 to 10 days from the initial chill

Pneumococci can be recovered from the blood in a variable proportion of cases the reported incidence of bacteremia depending in good part on the frequency with which cultures are made and the technic followed In the large series of cases compiled by Heffron (1939) bacteremia occurred in 26 per cent Persistent and increasing bactere mia are grave prognostic signs

Before the introduction of chemotherapy empyema was the commonest complication of lobar pneumonia occurring in approxi mately 3 per cent of patients (Heffron) Adequate antimicrobial therapy has made it a rarity

The evidence indicates very strongly that spontaneous recovery from pneumococcal pneumonia is dependent on the development of type specific antibody which can be demonstrated usually in the blood at about the time of crisis However it should be re membered that the antibody demonstrable in the circulating blood represents the excess left over after combination with type specific polysaccharide present in the lung and other organs of the body In other words antibody is being formed before recovery is apparent but appears in sufficient excess at that time so that it can be detected in the blood serum

LABORATORY DIAGNOSIS

The effective use of specific serum therapy for treatment of pneumococcal pneumonia necessitated rapid and accurate methods of etiologic diagnosis Of the many methods de scribed the Neufeld quellung or capsular swelling reaction is the simplest and best Neufeld observed in 1902 that when pneu mococci of a particular type and homologous antiserum are mixed together the capsules of the organisms become greatly swollen and in this state are clearly visible under the microscope The swelling is due to combina tion of specific antibody with the capsular polysaccharide

Sputum is emulsified by drawing it re peatedly into a syringe Then it is stained by Gram s method to determine whether organ isms having the morphology of pneumococci are present Loopfuls of emulsified sputum are mixed with a loopful of the various specific antipneumococcal sera a loopful of methylene blue is added to make the somatic portion of the cells more easily visible and the preparation is examined immediately under the oil immersion lens In a positive reaction the pneumococcal capsule has a greatly swollen appearance it becomes more refractile and its border is sharply delimited from the surrounding medium The quellung reaction can be used to identify pneumococci directly in sputum in spinal fluid and in the exudates from experimentally infected ani mals and when grown in artificial culture media Under the latter circumstances young cultures should be examined since in older cultures much of the capsular material diffuses away from the pneumococci into the surrounding medium so that capsular swell ing is less striking Although wet prepara tions of sputum or exudates are generally used it should be noted that the quellung reaction can also be carried out by applying specific antiserum to dried smears on glass slides

Diagnosis can also be made by injecting mice intraperitoneally with sputum In gen eral pneumococci are much more pathogenic

for the mouse than other organisms present in sputum or saliva and consequently come to predominate within a few hours in both the peritoneal exudate and the blood of the mouse On death of the mouse which usually occurs within 16 to 48 hours following injection of sputum, some of the peritoneal exudate is removed examined microscopically after Gram staining and then typed by the quellung reaction Pneumococci can usually be recovered in pure culture from the heart blood of the infected mouse It is good practice to make cultures of the heart blood for confirmatory studies

Pneumococci can be typed also by agglutination and precipitin reactions but the simplicity and the great accuracy of the quellung reaction make it a preferable technic

Culture of the blood of patients with pneumonia is important from the diagnostic point of view but even more so as a guide in prognosis

SPECIFIC SERUM THERAPY

Pneumococcal pneumonia is one of the few infectious diseases for which effective specific serum therapy was evolved The introduction of sulfonamide drugs in 1937 and the many antibiotics since that time have entirely displaced antiserum in therapy because they are more effective and much easier to use However a description of serum therapy is given because of its historical interest as well as the general principles which it illustrates The basis for serum therapy was laid in the fundamental studies of Avery Chickering Cole and Dochez (1917) who first showed convincingly that the antiserum to be used must be type specific that antibody must be given in adequate amounts and that it is most effective when administered early in the course of the disease Applied originally to treatment of pneumonia caused by Types I and II highly potent antisera later became available commercially for pneumonia caused by the majority of pneumococcal types (for summaries see Bullowa 1937, and Lord and Heffron 1938)

The earliest antisera were prepared by the immunization of horses with killed pneumococci and were administered intravenously in unconcentrated form Subsequently various methods were developed for refining and concentrating the antibody globulins in the crude serum which greatly facilitated treatment The introduction of rabbits for preparing antipneumococcal serum for therapeutic purposes was another advance since in general higher titers of antibody could be obtained (Horsfall *et al* 1937)

The dosage of type specific antipneumococcal serum can be controlled by determining whether the patient s blood and tissues contain an excess of antibody Specimens of blood serum obtained at intervals after treatment can be tested for free antibody by means of agglutination reactions with suspensions of homologous pneumococci Dosage of antiserum is adjusted so that an excess of antibody is constantly present in the blood However, a more useful method is the skin test with the purified specific capsular polysaccharides described by Francis (1933) 0 1 mg of homologous specific capsular polysaccharide dissolved in 0 1 ml of saline is injected intracutaneously If circulating antibody is present a wheal and erythema reaction appears at the site of polysaccharide injection within 15 or 30 minutes The wheal and erythema are due to the combination locally of polysaccharide and homologous antibody As early as possible in the course of the disease antibody is administered intravenously in an amount sufficient to result in a positive polysaccharide skin test In most instances defervescence and the onset of recovery occur within a few hours after sufficient antibody has been given At intervals of a few hours after serum therapy was first given the polysaccharide skin test is repeated in order to make sure that antibody remains present in excess

The ability to make a rapid etiologic diagnosis by means of the quellung reaction the preparation of highly concentrated preparations of specific antibody and the control of dosage by the polysaccharide skin test together made the serum treatment of pneumococcal pneumonia highly effective On the other hand the specialized nature of the technics involved the necessity for maintaining stocks of many type specific

antisera and the constant fear of anaphylactic reactions following intravenous administration of foreign protein prevented the serum treatment of pneumococcal pneumonia from achieving general use

CHEMOTHERAPY

Of bacteria causing human infections pneumococci are among the most susceptible to the action of antimicrobial drugs More over with the exception of the sulfonamides the appearance of drug resistance has been a rare occurrence during the course of therapy and up to the present time has caused little difficulty Resistance of pneumococci to sulfonamides has been encountered especially in patients treated with inadequate dosage and in cases in which a purulent complication such as empyema was present Penicillin the tetracycline compounds and chloramphenicol are more effective agents in treating pneumococcal infections and have largely displaced the sulfonamides although the latter are considered a useful adjunct in treating cases of meningitis Pneumonia due to tetracycline resistant strains of pneumococci has been reported recently in England and the United States

For respiratory tract infections penicillin remains the drug of choice because it is bactericidal and also because the capacity of pneumococcus to develop resistance to penicillin in vivo is extremely limited There is no authenticated instance recorded of therapeutic failure in a pneumococcal infection treated with penicillin as the result of resistance of the bacteria to the drug

It is instructive to compare the mechanism of action of specific serum therapy and chemotherapy in combating pneumococcal infections Spontaneous recovery from pneumococcal pneumonia is associated with the appearance of specific antibody in the blood over and above the amount required to combine with the capsules of the organisms and thus render them susceptible to phagocytosis Therefore in the natural disease there is a competition between the capacity of the pneumococci to grow and produce SSS and the ability of the infected person to form antibody to it Treatment with specific antiserum tips the balance in favor of the host since sufficient antiserum can be given in a short time to combine with all the SSS present both that which is on the surface of the microorganisms and that which is free in the blood and the tissues

The sulfonamide drugs which are essentially bacteriostatic act by restraining the growth of the organisms until sufficient antibody has been formed in the body to assure opsonization and phagocytosis of the pneumococci The participation of specific immunity appears to be necessary for a successful outcome in sulfonamide therapy

In the case of penicillin which is a bactericidal compound when used in a full therapeutic dosage the development of specific antibody seems to play a less significant part in recovery in the natural disease in man or in experimental infections of the highly susceptible mouse (MacLeod and Stone 1945) The role of a specific antibody response in recovery following treatment with the bacteriostatic tetracycline compounds has not been studied adequately

EPIDEMIOLOGY OF PNEUMOCOCCAL PNEUMONIA

As noted above pneumococcal pneumonia occurs almost always secondary to injury to the respiratory mucosa caused by an unrelated agent such as a viral infection or an irritating gas Furthermore the virulence of the various pneumococcal types for man differs greatly Types I and II have the most pronounced human virulence since between them they cause about half of all the cases of lobar pneumonia in the adult On the other hand certain other types are encountered very rarely as the cause of pneumonia and hence can be considered to be of low human virulence Therefore it should be apparent that the chances of developing pneumococcal pneumonia depend in great part on whether or not the nonimmune individual is a carrier of one of the more highly pathogenic pneumococcal types at the time he acquires a viral infection of the respiratory tract such as the common cold or influenza There is ample evidence (summarized by Heffron 1939) that when pneumococcal pneumonia is epidemic in a community it is always associated with a high

carrier incidence of the pneumococcal types causing disease Significantly, most epidemics of pneumococcal pneumonia reported in the literature have been caused by the same types that are responsible for most cases of endemic pneumonia Types I, II, IV, V and VII Under normal circumstances the incidence of carriers of the highly pathogenic types is relatively low However, if a high carrier incidence of pathogenic types prevails at a time when viral infections of the respiratory tract are epidemic epidemic pneumococcal pneumonia is liable to occur also (Hodges and MacLeod 1946)

Chance would appear to determine whether the nonimmune individual becomes a carrier of one or more types of the pneumococci (Hodges *et al* 1946) although the immune person is less capable of becoming a carrier than the nonimmune (MacLeod *et al* 1945)

Most reported epidemics of pneumococcal pneumonia have occurred in relatively closed communities such as mental hospitals, prisons and military installations The living conditions in such circumstances appear to favor the dissemination of the more pathogenic types once the latter are introduced into the community In addition the incidence of pneumococcal pneumonia is higher in workers in certain occupations such as in steel mills and in coal mines than in the general population (Heffron 1939)

There is evidence that the normal carrier is of more importance in the dissemination of the infective types than the patient ill with pneumonia (MacLeod *et al*, 1945)

PREVENTION OF PNEUMOCOCCAL PNEUMONIA

From the observations cited in relation to the epidemiology of pneumococcal pneumonia, it seems likely that control can be achieved either by preventing the nonbacterial respiratory infections which predispose or else by specific prophylaxis of pneumococcal infections themselves A certain amount of success has been achieved through both approaches

In recent years evidence has been presented that the incidence of influenza can be greatly reduced by immunization with vaccines of influenza virus types A and B, provided that the strains of virus present in the vaccine are closely related immunologically to the strains of virus causing epidemic influenza Therefore improvement in influenza vaccines and their general use might be expected to cause a reduction not only in influenza but also in pneumococcal pneumonia which occurs secondary to influenza Similarly the development of specific immunizing preparations for other viral infections of the respiratory tract should lead to a concomitant reduction in pneumococcal infections

Repeated attempts have been made to immunize against pneumococcal pneumonia (for review see Heffron 1939) In earlier trials the vaccines consisted of heat killed pneumococci which were injected subcutaneously Although proof was lacking the general opinion of those who employed whole bacterial vaccines was that a beneficial result was obtained The evidence of Lister and Ordman (1935) in South Africa was especially suggestive of a prophylactic effect In more recent years preparations of the capsular polysaccharides have been used following the demonstration by Francis and Tillett in 1930 that the isolated polysaccharides are antigenic for man Again suggestive evidence was obtained especially through the studies of Felton (Ekwurzel *et al* 1938) that immunization of man with the capsular polysaccharides prevents pneumococcal pneumonia Most of the studies on antipneumococcal immunization have been inadequate in one or more respects especially because of failure to determine whether the apparent reduction in pneumonia was confined to the types against which immunization was practiced as well as failure to design the experiment so that adequate controls were included

Most of the deficiencies inherent in previous attempts at immunization against pneumococcal pneumonia appear to have been avoided in the studies reported by MacLeod Hodges Heidelberger and Bernhard (1945) who have presented what may be considered as reasonably conclusive evidence that immunization by subcutaneous injection of purified capsular polysaccharides can prevent pneumococcal pneumonia

Immunization was carried out in an Army

camp where Types I II IV V VII and XII pneumococcal pneumonia had been epidemic for 2 years A dose of 0 06 mg of each of the capsular polysaccharides of pneumo coccus Types I II V and VII was injected subcutaneously into half the population the remainder serving as controls In the immu nized men occurrence of pneumonia caused by Types I II V and VII ceased within 2 weeks after immunization but continued in the nonimmunized controls The incidence of pneumonia caused by pneumo occal types other than those represented in the vaccine was not affected in either group

Although Types I II V and VII pneumo cocci continued to cause disease in the non immune group the incidence was not so high as was expected on the basis of the previous 2 years experience moreover the incidence of pneumonia caused by Type XII and other types was unaffected Therefore it is likely that immunization of one half the population protects not only those who are immunized but also affords a measure of protection to the nonimmune segment Partial protection of the nonimmune portion of the population may be explained by the observation that the immunized individual is less capable of car rying homologous pneumococci in the phar ynx than the nonimmune and because of the reduction in carriers dissemination of pneumococci is reduced

Large scale immunization of a civilian population by means of specific polysac charides has not been employed for the prevention of pneumococcal pneumonia

staphylococcus from the Greek *staphule* = a bunch of grapes

The ability of staphylococci to induce abscess formation in man was established by Garré (1885) and others who inoculated or rubbed staphylococcal cultures into the skin and recovered the organism from the localized pustules which formed

On the basis of colonial pigmentation 3 species of staphylococci were recognized *Staph aureus Staph albus* and *Staph citreus* (Rosenbach 1884 Passet 1885) Most strains isolated from human lesions produced the golden yellow *aureus* pigment whereas colonies of the usually nonpathogenic staphylococci were white (*albus*) or lemon yellow (*citreus*) However since colonies of pathogenic strains were sometimes white it became apparent that colonial pigmentation alone would not suffice for classification Studies on the physiologic and the biochemical attributes of the staphylococci also failed to provide a firm basis for species differentiation The early observations of Loeb (1903) and Much (1908) that cultures of *Staph aureus* coagulate plasma were extended and coagulase production is now the most useful criterion for identification A staphylococcus that produces coagulase is now termed *Staph aureus* irrespective of colonial pigmentation (Breed *et al* 1957) However the general problem of taxonomy of staphylococci and micrococci remains quite complex (Cowan 1962)

Staphylococcal disease although of relatively frequent occurrence received less attention in the early decades of the 20th century than did the more dramatic diseases caused by other pyogenic cocci Interest in staphylococci was stimulated considerably as a result of the Bundaberg disaster (Report of the Royal Commission 1928) Bundaberg a city in Australia was threatened with a diphtheria epidemic and toxin antitoxin mixtures were administered for prophylaxis One vial kept at room temperature in the summer heat without a preservative was used to inoculate 21 children Within several hours 16 of them became acutely ill and 12 died within 2 days with symptoms of septicemia or toxemia *Staph aureus* was recovered both from the vial and from lesions

Studies on the toxic effects of staphylococci and their products in animals led to the proposal that α hemolysin present in culture filtrates was responsible for lethality as well as dermonecrosis (Burnet 1929) For a time the clinical use of staphylococcal toxoid and antitoxin was in vogue but results were disappointing

The inability to incriminate a single product component or property of *Staph aureus* as the determinant of pathogenicity is a recurring feature in the history of research on staphylococcal disease Included in the list of substances or characteristics which have been advanced as primary factors are coagulase α toxin and hemolysins leukocidin lipase hyaluronidase and other enzymes and the ability of the organisms to resist phagocytosis or to multiply within phagocytic cells In each instance proponents have been unable to gather sufficient evidence to establish the role of the proposed mechanism Only the ability of staphylococcal enterotoxin to induce food poisoning but not invasive disease remains intact in the legacy of this search

In 1928 Alexander Fleming contracted to write on The Staphylococci for a systematic treatise on bacteriology Requiring more information on the variation of *Staph aureus* agar cultures he restudied the problem During this investigation a phenomenon was noted which was described in the text of the treatise (1929) as follows A common laboratory contaminant a *Penicillium* has a very marked lytic action on staphylococci growing in its neighborhood It is one of the ironies in the history of bacterial disease that the organism on which the effect of penicillin was originally seen had the capacity to produce an enzyme capable of destroying penicillin Over the course of time penicillinase producing penicillin resistant *Staph aureus* strains have become responsible for a significant proportion of staphylococcal disease The same phenomenon has occurred after the introduction of other antibiotics—fully pathogenic resistant strains have replaced susceptible strains of *Staph aureus*

Morphology

In stained preparations of pus *Staph aureus* appears as irregular groups of cocci

17

Staphylococci and Other Micrococci

STAPHYLOCOCCUS AUREUS

Staphylococci are facultatively anaerobic, nonmotile gram positive cocci that tend to grow in irregular clusters Two species *Staph aureus* and *Staph epidermidis*, are currently recognized and they constitute a genus in the family Micrococcaceae (Breed *et al* 1957) *Staph aureus (Staph pyogenes M pyogenes* var *aureus)* is responsible for a variety of clinical disorders in man and animals ranging from pustules to food poisoning to fulminating septicemia However *Staph aureus* is also encountered as a normal inhabitant of human skin and mucous membranes in the absence of overt disease Although most strains produce a number of biologically active toxins and enzymes the mechanisms underlying the development and the persistence of disease are poorly understood Interest in the pathogenesis of staphylococcal disease has been aroused in recent years by an apparently increasing incidence of severe illness particularly in hospital environments where many strains are insensitive to the antimicrobial agents which have so successfully curbed the morbidity and the mortality of disease caused by other pyogenic cocci

History

In the latter half of the 19th century spherical microorganisms were repeatedly observed in suppurative lesions Bilroth (1874) recognized the diverse arrangement of the cocci and classified them as monococcus, diplococcus streptococcus and gliacoccus He postulated that all were forms of one organism, *Coccobacteria septica* and that their presence in pus was a secondary event and not of etiologic significance Koch (1878) found this view untenable and demonstrated at least 6 different disease syndromes in experimental animals injected with purulent material In each instance organisms identical with those originally present were recovered from the experimental lesions Koch s thesis regarding the induction of specific disease by specific microorganisms was substantiated with respect to abscess formation by both Pasteur (1880) and Ogston (1881)

Pasteur noted the presence of small spherical units, sometimes in pairs rarely in tetrads but most usually associated in small masses in pus from furuncles He also found entirely similar organisms in the contents of an osteomyelitic lesion leading him to state that osteomyelitis is a furuncle of the osseous medulla Studies in experimental animals supported the contention that both superficial and deep seated disease could be produced by the furunculosis organism

Ogston examined aspirated fluid from 82 abscesses and found cocci in all but 13, these 13 were cold abscesses Injection of pus containing the cocci produced either septicemia or localized suppuration in experimental animals Ogston noted that the cocci sometimes were found in chains whereas on other occasions clumps of cocci were seen Because of their aggregation he called the latter

species of blood used and the organism ex amined Rabbit blood is usually employed because erythrocytes of that animal are mark edly sensitive to the α hemolysin produced by most strains of *Staph aureus* isolated from human infections

Variation

Staph aureus shows a wide variation in biologic properties both in nature as well as after laboratory manipulations In any given culture colonies may appear with altered pig mentation qualitative and quantitative dif ferences in production of diffusible toxins and enzymes and varying susceptibilities to bac teriophage and to antimicrobial agents

Of particular interest are the small colony G (gonidial) forms of *Staph aureus* G forms of *Staph aureus* were first noted on agar subcultures of organisms grown in broth containing lithium chloride (Hoffstadt and Youmans 1932) and are also produced in media containing antibiotics particularly penicillin (Wise and Spink 1954 Wise 1956) Bacteriophage resistant cells in a sensitive culture also may form G colonies (Smith 1953) G colonies are pinpoint and nonpigmented have a high thermal death point do not produce α hemolysin form little or no free coagulase and are resistant to antibiotics They do not require hypertonic media for growth Reversion occurs after a varying period of time following removal of the inducing material some G colonies have remained stable for many months The indi vidual cells appear to be normal except for a few swollen forms G colonies do not pro duce lesions in experimental animals but per sist in tissues for several weeks G colonies have been isolated from lesions of untreated patients as well as from those who have re ceived antibiotic therapy

L forms have also been isolated from staphylococci grown in penicillin They dif fer from G colonies morphologically in their requirement for hypertonic conditions for initial growth and also in their ability to grow well under anaerobic conditions (Matt man *et al* 1961 Marston 1961a b) Sub cultures of L forms can grow in low salt con centrations and in the absence of penicillin for a number of weeks before reversion oc curs Like G colonies the L forms are non hemolytic and insusceptible to bacteriophage lysis coagulase production is also diminished

It is likely that cells of G and L forms are deficient in cell wall material and that this deficiency is more marked in L forms which require hypertonic media for primary isola tion Osmotically fragile protoplasts which are completely devoid of cell wall material can be prepared with lysozyme from the few strains of *Staph aureus* susceptible to this cell wall dissolving enzyme

Biochemical Reactions

The type strain of *Staph aureus* (Cowan *et al* 1954) liquefies gelatin in 24 hours at 27 C Milk is acidified at 37° C in 1 day with clot formation and liquefied and di gested at 5 and 7 days respectively The methyl red test is positive Acetoin is pro duced from glucose (positive Voges Pros kauer test) nitrates are reduced to nitrites catalase urease and phosphatase activities are found acid is formed from glucose xylose lactose sucrose maltose glycerol and mannitol whereas neither dulcitol nor salicin is fermented Again individual *Staph aureus* strains vary considerably from the type strain in their range of biochemical and enzymatic activities

Classification

Strain or type specific antigens of *Staph aureus* are unknown and the agglutination procedures commonly employed in serologic classification depend on the reactivity of sev eral distinct antigens Cowan (1939a) classi fied 70 per cent of strains into 3 major ag glutinating groups and since then additional groups have been defined (Christie and Keogh 1940 Hobbs 1948) At present 13 serotypes are recognized Other workers rather than utilizing a restricted number of serotypes have arbitrarily designated agglu tinating factors and strains are identified by the specific factors they possess (Oeding 1960 Pillet *et al* 1961) The factors do not necessarily represent single agglutinogens and some are known to consist of several antigens In both systems it is of crucial im portance to prepare appropriately absorbed antiserum specific for the particular serotype or factor Slide agglutination rather than the tube test, is generally used Serologic typing

single elements, pairs tetrads and short chains may also be seen The formation of *irregular masses* is most marked on agar cultures and is less prominent in liquid media Staphylococci divide in irregular fashion in two planes at right angles to each other resulting in the formation of clumps

The individual cocci are quite uniform in size 0 8 to 1 0 micron in diameter and in general are smaller than the saprophytic micrococci Neither flagellae nor spores are present The cocci are spherical but their opposing surfaces may appear to be somewhat flattened

Staph aureus is strongly gram positive but individual cells in old cultures may lose the ability to retain the gram stain In infected material staphylococci ingested by phagocytic cells may be gram negative

Encapsulation of *Staph aureus* has been a matter of dispute Lyons (1937) claimed that in broth cultures capsules were present within the first few hours of growth but disappeared after incubation for 24 hours This finding was not confirmed by others (Spink, 1939) Price and Kneeland (1954 1956) isolated a mucoid encapsulated variant of *Staph aureus* after passage of the parent organism through embryonated eggs Addition of homologous antiserum produced a prompt quellung phenomenon A capsular antigen has been isolated from culture filtrates of the encapsulated mucoid Smith strain of *Staph aureus* but is present in only a few biologically similar strains (Morse 1962a 1963a) Thus some strains of *Staph aureus* are clearly encapsulated but most show no capsule and no relationship has been established between capsule formation and pathogenicity

The fine structure of *Staph aureus* as revealed by electron microscopic examination is similar to that of most other gram positive organisms (Suganuma 1961) The finely granular cytoplasm is surrounded by a delicate membrane which is clearly separated from the thick rigid overlying cell wall Thus far morphologic substructure of the cell wall of *Staph aureus* has not been demonstrated

Cultivation

Staph aureus grows readily in a variety of conventional nutrient media Essential growth factors have been delineated through the use of chemically defined media (Fildes *et al* 1936) Amino acid requirements vary from strain to strain but cystine valine glycine proline aspartic acid and leucine are usually necessary (Gladstone, 1937 Bondi *et al* 1954) Thiamine and nicotinic acid are essential for aerobic growth (Knight, 1937) and uracil is required in anaerobic cultures (Richardson 1936) Biotin and pantothenic acid stimulate growth of some strains (Gretler *et al* 1955) Optimal growth temperature is 36° C to 38° C but the organism will multiply readily at temperatures from 10° C to 45° C Many strains of *Staph aureus* grow over a wide range of pH 4 8 to 9 4 though the optimum is near neutrality

Broth cultures are usually smooth but occasional strains yield a granular appearance After a few days the organisms begin to settle out and a scum often appears on the surface On storage of broth cultures in the refrigerator the cocci frequently form a viscid stringy mass

Individual colonies on agar are round convex and 1 to 4 mm in diameter with a sharp border Most strains are not mucoid Pigment which does not occur in broth or under anaerobic conditions is discerned most satisfactorily on agar plates left at room temperature for 24 to 48 hours after initial culture at 37° C for 24 hours If direct determination of the colonial coloration is difficult it can be assessed further by transferring a portion of the colony to a white surface and examining it after the organisms have dried

Pigment production by *Staph aureus* varies from white to orange depending on the strain and the media used The golden yellow pigment which is most commonly found is due to the carotenoids δ-carotene and rubixanthene (Sabin and Stahly 1942 Suzue and Tanaka 1959) Enhanced pigment production is obtained by the addition of carbohydrates milk or glycerol monoacetate (Willis and Turner 1962) On blood agar plates colonies of *Staph aureus* frequently are surrounded by zones of clear hemolysis Since *Staph aureus* can produce 3 distinct hemolysins with different lytic spectra the extent of hemolysis depends both on the

species of blood used and the organism ex amined Rabbit blood is usually employed because erythrocytes of that animal are mark edly sensitive to the α hemolysin produced by most strains of *Staph aureus* isolated from human infections

The individual cocci are quite uniform in size 0 8 to 1 0 micron in diameter and in general are smaller than the saprophytic micrococci Neither flagellae nor spores are present The cocci are spherical but their opposing surfaces may appear to be somewhat flattened

Staph aureus is strongly gram positive but individual cells in old cultures may lose the ability to retain the gram stain In infected material staphylococci ingested by phagocytic cells may be gram negative

Encapsulation of *Staph aureus* has been a matter of dispute Lyons (1937) claimed that in broth cultures capsules were present within the first few hours of growth but disappeared after incubation for 24 hours This finding was not confirmed by others (Spink 1939) Price and Kneeland (1954 1956) isolated a mucoid encapsulated variant of *Staph aureus* after passage of the parent organism through embryonated eggs Addition of homologous antiserum produced a prompt quellung phenomenon A capsular antigen has been isolated from culture filtrates of the encapsulated mucoid Smith strain of *Staph aureus* but is present in only a few biologically similar strains (Morse 1962a 1963a) Thus some strains of *Staph aureus* are clearly encapsulated but most show no capsule and no relationship has been established between capsule formation and pathogenicity

The fine structure of *Staph aureus* as revealed by electron microscopic examination is similar to that of most other gram positive organisms (Suganuma 1961) The finely granular cytoplasm is surrounded by a delicate membrane which is clearly separated from the thick rigid overlying cell wall Thus far morphologic substructure of the cell wall of *Staph aureus* has not been demonstrated

CULTIVATION

Staph aureus grows readily in a variety of conventional nutrient media Essential growth factors have been delineated through the use of chemically defined media (Fildes et al 1936) Amino acid requirements vary from strain to strain but cystine valine glycine proline aspartic acid and leucine are usually necessary (Gladstone 1937 Bonde et al 1954) Thiamine and nicotinic acid are essential for aerobic growth (Knight, 1937) and uracil is required in anaerobic cultures (Richardson 1936) Biotin and pantothenic acid stimulate growth of some strains (Gretler et al 1955) Optimal growth temperature is 36° C to 38° C but the organism will multiply readily at temperatures from 10° C to 45° C Many strains of *Staph aureus* grow over a wide range of pH 4 8 to 9 4 though the optimum is near neutrality

Broth cultures are usually smooth but occasional strains yield a granular appearance After a few days the organisms begin to settle out and a scum often appears on the surface On storage of broth cultures in the refrigerator the cocci frequently form a viscid stringy mass

Individual colonies on agar are round convex and 1 to 4 mm in diameter with a sharp border Most strains are not mucoid Pigment which does not occur in broth or under anaerobic conditions is discerned most satisfactorily on agar plates left at room temperature for 24 to 48 hours after initial culture at 37° C for 24 hours If direct determination of the colonial coloration is difficult it can be assessed further by transferring a portion of the colony to a white surface and examining it after the organisms have dried

Pigment production by *Staph aureus* varies from white to orange depending on the strain and the media used The golden yellow pigment which is most commonly found is due to the carotenoids δ-carotene and rubixanthene (Sabin and Stahly 1942 Suzue and Tanaka 1959) Enhanced pigment production is obtained by the addition of carbohydrates milk or glycerol monoacetate (Willis and Turner 1962) On blood agar plates colonies of *Staph aureus* frequently are surrounded by zones of clear hemolysis Since *Staph aureus* can produce 3 distinct hemolysins with different lytic spectra the extent of hemolysis depends both on the

insoluble residue is the structured mucopeptide which confers spatial configuration to the bacterial cell In common with the mucopeptide of the cell walls of other gram positive organisms the mucopeptide of *Staph aureus* walls consists of a limited number of amino acids and the amino sugars N acetyl glucosamine and N acetylmuramic acid The amino acids characteristically present are alanine glutamic acid lysine and glycine

Antigenic specificity of the teichoic acid resides in the N acetylglucosamine moieties (Morse 1962c Nathenson and Strominger 1962) The amino sugar may be in either α or β glycosidic linkage and both configurations may confer immunologic specificity The heterogeneity requires that antisera utilized for the detection of the antigen recognize both configurations Polysaccharide A is a determinant of cell wall agglutination but it does not play a role in the agglutination of the intact organism It has been suggested that antibodies against *Staph aureus* cell wall teichoic acid i e Polysaccharide A are required for efficient phagocytosis (Mudd *et al* 1963)

An immediate skin reaction occurs in most adults after intradermal injection of Polysaccharide A fewer reactions are seen in children Low levels of precipitating antibodies are present in the majority of adult sera and higher levels are found in sera of patients with severe staphylococcal disease

Antigen A Another widely distributed antigenic component of *Staph aureus* is a protein termed Antigen A originally described by Verwey (1940) and further studied by Jensen (1958) and others (Lofkvist and Sjoquist 1962) Antigen A is a constituent of the cell wall and is released from the walls into solution by deoxyribonuclease (Yoshida *et al* 1963) It is a basic protein with a molecular weight of about 13 000 and it is destroyed by trypsin or chymotrypsin Antigen A is found in a majority of *Staph aureus* strains with the notable exception of the Wood 46 strain used in the commercial production of toxoid and is an important factor in the agglutination of intact bacterial cells Absorption of agglutinating antisera with Antigen A significantly reduces the agglutinin titer against a variety of strains of *Staph aureus* and thus the antigen is of no taxonomic value (Lenhart *et al* 1963) Its biologic properties in vivo are unknown but impure preparations are toxic for the isolated guinea pig ileum The antigen although an agglutinogen apparently plays no role in the phagocytosis of *Staph aureus* Antibodies against Antigen A are invariably present in normal human sera but are not found in normal rabbit sera

Capsular Antigen Homogeneous capsular material has been isolated from culture supernatant fluids as well as from bacterial cells of the distinctive mucoid Smith strain commonly used for experimental purposes The antigen is found in only a few strains of *Staph aureus* which have in common with the Smith strain a mucoid colonial appearance inability to be typed by bacteriophage and absence of bound coagulase (Morse 1962a 1963) The major structural unit of the antigen is 2 aminoglucuronic acid variable amounts of amino acids are also present (Perkins 1963 Haskell and Hanessian 1963)

Immunologically reactive polysaccharide material has been obtained from the supernatant fluid of stored cultures of *Staph aureus* Chemical analysis suggests that this represents polyglycerophosphate released from within the cell rather than true capsular antigen (Wiley and Wonnacott 1962)

Polyglycerophosphate ("Intracellular" Glycerol Teichoic Acid) Polyglycerophosphate first identified as an antigenic component of streptococci is found in many gram positive organisms including the staphylococci (McCarty 1959) The exact localization of polyglycerophosphate is unclear but it is not found in the cell walls and hence is termed an intracellular glycerol teichoic acid The antigen readily diffuses from the bacterial cell and it or related compounds represents a heterophile erythrocyte sensitizing antigen found in the culture supernatant fluids of *Staph aureus* and other gram positive organisms (Gorzynski *et al* 1960) Both unsubstituted polyglycerophosphate and chains with D alanyl units in labile ester linkage have serologic activity *Staph aureus* also contains glycerol teichoic acids with sugar substituents but their serologic activity is unknown (RajBhandary and Baddiley 1962)

has proved to be useful in epidemiologic studies but the multiplicity of ill defined agglutinogens the presence of blocking antigens, antigenic overlap and difficulties in preparing proper antisera preclude general usefulness Moreover differences in agglutination reactions may reflect only quantitative rather than qualitative differences in antigenic composition (Stern and Elek 1957) Attempts to distinguish between *Staph aureus* strains by precipitin hemagglutination and complement fixation reactions have been unsuccessful

In the absence of precise and practical methods of serologic differentiation bacteriophage typing of *Staph aureus* is utilized extensively Since Fisk s (1942) initial studies, the usefulness of this method has been extended by the selection of bacteriophages with restricted host range and by standardization of technics (Blair and Williams 1961 Wentworth 1963) From the large number of known lytic phages only a basic working set is generally used for routine typing

Group I 29, 52, 52A 79 and 80

Group II 3A 3B 3C 55 and 71

Group III 6 7, 42E 47 53 54, 75 77 and 83A

Group IV 42D

Miscellaneous 81 and 87

The phages in each group have similar host ranges and a given culture of *Staph aureus* is often lysed by more than one phage in a group occasionally a strain is lysed by bacteriophages in more than one group The phages in each group tend to be serologically related The mechanism determining specific susceptibility to bacteriophage is uncertain but it does not appear to be due to different receptor substances (Rountree 1947 Morse, 1962b) It is of interest that there is a rough correlation between serologic typing and bacteriophage typing (Oeding and Williams 1958) Certain biologic characteristics are also correlated with phage type e g the prevalence of multiple antibiotic resistance in strains typed by Groups I and III phages (Knight and Holzer 1954, Barber and Burston 1955)

In practice a culture of *Staph aureus* is flooded or swabbed onto an agar plate, and after drying bacteriophage suspensions are applied as fine drops at suitable distances from each other After incubation for 18 hours at 30° to 32° C, the bacteriophage strains which produce definite lysis are recorded and the phage pattern assigned to the organism e g, an organism lysed by phages 52A, 79 and 80 is designated as phage type 52A/79/80 The dilution of bacteriophage applied is that which just fails to give confluent lysis of the propagating strain—the routine test dilution or RTD Ten to 30 per cent of *Staph aureus* strains are not typable at the RTD but some of these are lysed at higher phage concentrations

Bacteriophages also exert a profound influence on the biology of *Staph aureus* The vast majority of strains are lysogenic and the existence of prophage affects such diverse properties as susceptibility to lytic phage production of various enzymes and hemolysins and resistance to antibiotics Transduction of these properties can be achieved in vitro (Morse, 1959, Rountree 1949 Blair and Carr 1961, Morse and La Belle 1962 Pattee and Baldwin 1962)

Staph aureus strains can also be distinguished by differences in susceptibility to various antibiotics and the determination of antimicrobial sensitivity serves as a useful adjunct to bacteriophage or serologic typing

Antigenic Structure

Polysaccharide A (Cell Wall Teichoic Acid) A species specific polysaccharide was isolated from virulent staphylococci by Julianelle and Wieghard (1935, Wieghard and Julianelle 1935) This antigen called Polysaccharide A recently has been identified as a carbohydrate component of the cell wall of *Staph aureus* (Haukenes *et al* 1961 Mc Carty and Morse 1964) It belongs to the group of bacterial polyolphosphate polymers called teichoic acids and consists of a backbone chain of ribitol linked 1 5 by phosphodiester bridges to form polyribitol phosphate (Baddiley 1962) N acetylglucosamine is in glycosidic linkage to C_4 of each ribitol and D alanine is in labile ester linkage to C_2 or C_3 of the ribitol residues Like the C polysaccharide of Group A streptococci Polysaccharide A is localized to the cell wall where it is attached by primary chemical bonds The antigen is solubilized by extracting the walls with trichloroacetic acid The

affects human as well as rabbit white blood cells leukocytes of other species are not susceptible Addition of leukocidin to suspensions of human granulocytes in the presence of calcium ions results in degranulation of the cells and the formation of cytoplasmic vesicles (Woodin *et al* 1963) Woodin (1959) found that P V leukocidin consists of 2 protein components both of which are required for leukotoxicity Antibody to either component protects against leukocyte damage (Gladstone *et al* 1962)

Free Coagulase Plasmas of many animal species are readily clotted by the extracellular or free coagulase of *Staph aureus* Free coagulase does not act directly to convert fibrinogen to fibrin but rather interacts with a plasma factor (coagulase reacting factor or CRF) to produce an active principle very similar to thrombin Both thrombin and the coagulase CRF principle release similar peptides from fibrinogen during clotting (Drummond and Tager 1963) Both have esterase activity (Haughton and Duthie 1959) and the esterase as well as the clotting properties are inhibited by diisopropylfluorophosphate but not by soybean trypsin inhibitor (Drummond and Tager 1962) However the coagulase-CRF factor differs from thrombin in not requiring calcium for its formation and in its relative insensitivity to heparin (Sanders 1963)

The plasmas of most animal species are susceptible to the action of free coagulase with the notable exceptions of the mouse and fowl which are deficient in CRF The action on guinea pig plasma is variable Studies on partially purified coagulase reveal it to be a heat labile protein which is destroyed by both trypsin and pepsin Less than 0 1 mcg will clot human plasma in 24 hours The intravenous injection of 22 mcg /kg is lethal for the rabbit, whereas 35 times that dose is required to kill mice (Duthie and Haughton 1958)

Coagulase is only weakly antigenic but at least 7 antigenically distinct staphylocoagulases have been recognized (Rammelkamp *et al* 1950 Duthie 1952 Zen Yoji *et al* 1961a b) There is a relationship between the type of coagulase produced by an organism and its bacteriophage type but no correlation exists with serologic classification

Bound Coagulase When *Staph aureus* cells are mixed with plasma on a glass slide thick clumps appear due to deposition of fibrin around the organisms The slide coagulase test correlates well with the tube coagulase test and originally it was believed that both reflected activity of the same product free coagulase It is now apparent that another coagulase bound coagulase is responsible for the positive slide test (Duthie 1954) Bound coagulase or clumping factor is not found in culture filtrates Antibody to bound coagulase prevents clumping of *Staph aureus* in plasma, and there is no inhibition by free coagulase antibodies Bound coagulase also differs from free coagulase in its spectrum of activity against various plasmas e g mouse plasma which is not efficiently clotted by free coagulase is readily coagulated by bound coagulase However the most significant difference between the two coagulases is that bound coagulase converts fibrinogen directly to fibrin without requiring an accessory plasma factor

Staphylokinase (Fibrinolysin) The fibrinolytic capacity of *Staph aureus* was recognized more than 50 years ago when it was noted that clots induced by staphylocoagulase lysed after several hours Lack (1948) demonstrated clearly that as in the case of streptococci clot dissolution by staphylococci is not the direct result of a bacterial fibrinolytic factor but is caused by activation of plasma plasminogen to the fibrinolytic enzyme plasmin For this reason the term staphylokinase is preferred to fibrinolysin Staphylokinase is formed by 70 to 90 per cent of strains and unlike streptokinase it activates plasminogen from many species and does not require plasma proactivator (Davidson 1960) Specific antibodies to staphylokinase inhibit its action on plasminogen (Quie and Wannamaker 1962) Staphylokinase is also responsible for the production of punctate areas of hemolysis and proteolysis which occur at a distance from colonies grown on blood agar the Muller phenomenon (Quie and Wannamaker 1961) Purified preparations of staphylokinase have not been obtained yet

Hyaluronidase Over 90 per cent of *Staph aureus* strains produce the enzyme hyaluronidase which depolymerizes mucopolysac

Other Antigens Immunodiffusion studies reveal that *Staph aureus* contains a multiplicity of other antigenic components which have not been isolated or characterized (Bernheimer and Schwartz 1961, Oeding and Haukenes 1963) Interestingly, antibody against one of these antigens is widely distributed in normal mammalian sera including that of germ free mice (Cohen *et al* 1963) Further studies may reveal a role for some of these antigens in pathogenicity as well as facilitating classification

TOXINS AND ENZYMES

α Toxin (α Hemolysin) Culture filtrates of many strains of *Staph aureus* lyse rabbit erythrocytes are lethal for experimental animals and produce local necrosis following intradermal injection It has long been suspected that one substance is responsible for these activities recent studies have confirmed this hypothesis (Bernheimer and Schwartz 1963, Lominski *et al* 1963) Purified α-toxin is a heat labile protein of molecular weight 44 000 As little as 0 008 mcg lyses a standard suspension of rabbit erythrocytes erythrocytes of sheep and humans are 25 and 150 times more resistant respectively Also 0 5 to 1 0 mcg of purified α toxin produces dermonecrosis and 4 0 mcg is lethal for the rabbit The precise mechanism of action of α toxin is not understood but it has no proteolytic activity Impure preparations cause marked contraction of smooth muscle followed by atony and flaccid paralysis striated muscle is not affected (Thal and Egner 1962)

Maximum amounts of α toxin are formed only after incubation for several days Yeast extract and increased carbon dioxide concentration appear to enhance production whereas anaerobiasis is inhibitory α Toxin is also formed in vivo The toxin is antigenic and toxoid is prepared by treating crude culture filtrates with formalin Anti α toxin blocks all of the biologic activity of the toxin

β Hemolysin, which is found more often in strains from animal sources is a hot cold hemolysin i e extensive lysis of erythrocytes does not occur during primary incubation at 37° C but does after subsequent storage at cold temperature (Glenny and Stevens 1935) Sheep ox and goat erythrocytes are markedly susceptible to β lysin whereas those of rabbit and man are resistant Divalent cations are required for hemolysis (Jackson 1963) Like α toxin β hemolysin is heat labile but production of the latter is not inhibited by anaerobiasis There is evidence that β lysin is a phospholipase which hydrolyzes sphingomyelin and that differences in the susceptibility of red blood cells from different species reflect the availability of this substrate (Doery *et al* 1963) β Hemolysin has less intrinsic toxicity for experimental animals than α toxin It is antigenic, and antitoxin prevents hemolytic activity

δ Hemolysin A third distinct hemolysin produced by *Staph aureus* is δ hemolysin (Williams and Harper 1947) which is considerably more heat stable in crude culture filtrates than α or β lysin Purified δ hemolysin is a trypsin sensitive protein with a molecular weight of approximately 70 000 (Yoshida 1963) It hemolyses human erythrocytes as well as those of the rabbit sheep erythrocytes are less susceptible Heated culture filtrates with δ hemolysin activity are not toxic but intravenous injection of concentrated material into rabbits is lethal (McLeod 1963) The most striking pathologic finding is an acute nephritic lesion The existence of a fourth hemolysin γ hemolysin has been postulated but many workers believe that it is identical with δ hemolysin (Smith and Price 1938 Elek and Levy 1950)

Leukocidins Three distinct leukocytotoxic substances can be found in culture filtrates of staphylococci The leukocidin described by Neisser and Wechsberg (1900) which agglomerates rabbit white cells and interferes with their respiration is identical with α toxin and has no effect on human leukocytes A thermostable leukocytotoxic substance termed leukolysin by Gladstone and van Heyningen (1957) causes marked morphologic changes in the leukocytes of all species examined except those of sheep Leukolysin is apparently identical with δ hemolysin The third leukocidin described by Panton and Valentine (1932) is not associated with hemolytic activity and is formed by approximately 40 to 50 per cent of strains The P V leukocidin or human leukocidin"

phosphatase (Barber *et al* 1951) and lipase and phospholipase (Magnuson *et al* 1962 Shah and Wilson 1963) Certain strains also produce an autolysin which differs from the lytic factor virolysin (Ralston *et al* 1957) produced during virulent phage infection

Ecology and Epidemiology

Staph aureus frequently is found in large numbers on normal human skin and mucous membranes and yet serious staphylococcal disease is comparatively rare Colonization begins in infancy within the first week to 10 days of life as many as 90 per cent of new borns are nasal carriers of *Staph aureus* Infants born at home acquire *Staph aureus* at a rate only slightly less than that found in hospital nurseries The carrier rate falls to about 20 per cent during the first 2 years of life but by age 4 to 6 it approaches the adult rate of 30 to 50 per cent (Williams 1963) The organism is found most com monly in the anterior nares and this is the site usually cultured in epidemiologic studies However significant skin carriage also oc curs particularly on the dorsum of the hands Usually the same phage type of *Staph aureus* is found both in the nares and on the skin of an individual carrier *Staph aureus* can also be isolated from throat cultures of asympto matic persons and intestinal carriage is esti mated at 20 to 30 per cent.

With respect to nasal carriage 3 kinds of individuals are recognized. Some 10 to 20 per cent of normal adults yield *Staph aureus* from the nose at all examinations and most keep the same phage type for many months or years (Roodyn 1960) An equal number of persons rarely harbor *Staph aureus* The majority of people are intermittent carriers That is they carry the organism for a period of a few weeks then are free from *Staph aureus* for a similar period and then once again are carriers often with a strain of a different phage type

The dynamics of acquisition are not fully understood but several important phe nomena have been observed As indicated the newborn rapidly acquires *Staph aureus* and in nurseries the strain carried is that predominant within the hospital unit (Barber *et al* 1953) The site of primary coloniza tion of the newborn is the umbilicus and the nasal carrier rate can be diminished markedly by maintaining sterility of the umbilical stump (Gluck and Wood 1961) Spread of the organism in the nursery is primarily by direct contact with personnel although it is well known that *Staph aureus* survives in fomites for long periods of time (Mortimer *et al* 1962)

Epidemics of suppurative disease in new born nurseries which are of considerable concern in many areas are usually associated only with certain strains of *Staph aureus* These strains designated hospital or "epi demic" strains are usually resistant to a variety of antibiotics Strains of the 80/81 complex became widely distributed in hos pitals throughout the world beginning in 1954 and were responsible for many nursery and other nosocomial epidemics other epi demic types usually in phage Groups I or III are also known (Parker and Jevons 1963) Even in the case of these epidemic strains healthy carriage among hospital personnel and patients is more frequent than is the occurrence of disease

In a nursery epidemic of staphylococcal disease as many as 50 per cent of infants will develop either superficial or deep sup-purative lesions (Shaffer *et al* 1957) The onset of disease may take place after dis charge from the nursery and it is not uncom mon for an infant to disseminate the hospital strain within the home and for lesions to de velop in family members particularly breast abscesses in nursing mothers (Hurst and Grossman 1960)

The acquisition and the carriage of *Staph aureus* by adults is a complex situation It is not known why certain persons are always carriers and why others are almost never carriers Moreover it is unclear why it is rare for a person to harbor more than one phage type of organism Most of the studies on the dynamics of the carrier state in adults have also been performed in hospital settings Ap proximately 20 to 30 per cent of patients admitted to hospitals will become carriers of the prevalent hospital strain the incidence of colonization increases with the duration of hospital stay (Noble *et al* 1964) Per sons who are already carriers have a lower acquisition rate than do those free of staph ylococci (Williams *et al* 1959) Acquisition

charides (Rogers, 1954) Hyaluronidase is antigenic and immunologic analyses thus far have revealed only one such enzyme in staphylococci

Penicillinase Many strains of *Staph aureus* particularly those lysed by bacteriophages in Groups I and III are resistant to penicillin Resistance is due to inactivation of penicillin by an enzyme penicillinase, which opens the β lactam ring of the penicillin molecule (Pollock, 1962) Penicillinase is a genetically constitutive enzyme but phenotypic expression i e the amount of enzyme formed is enhanced by the presence of the penicillin substrate Penicillinase production can also be increased by exposure of the organisms to some of the synthetic penicillins despite the fact that these compounds are only minimally susceptible to the enzyme (Batchelor *et al* 1963) Penicillinase formation has been demonstrated in strains isolated before the general use of the antibiotic suggesting that the current prevalence of penicillin resistant strains is the result of selection rather than recent mutation (Kirby 1944) Attempts to induce penicillinase formation in strains lacking the enzyme by exposing them to penicillin have been uniformly unsuccessful Penicillin resistance may develop in some strains treated in this manner but a different mechanism of resistance is apparently involved Moreover such strains in contradistinction to penicillinase producing organisms are unstable and nonpathogenic (Barber 1962) However penicillinase production can be induced in strains lacking the enzyme by transduction (Ritz and Baldwin 1961) Penicillinase producing *Staph aureus* may impair locally the action of *penicillin on other pathogens* (*Simon and* Sakai 1963)

Penicillinase may be found as either an endocellular or an exocellular product depending on the strain and the cultural conditions Purified exocellular penicillinase has been prepared recently (Richmond 1963)

Enterotoxin The majority of cases of food poisoning related to bacteria or bacterial products are caused by staphylococcal enterotoxin (Dack 1956) Enterotoxin is produced by only a few strains of *Staph aureus* and these are generally of phage type 6/47 or 42D (Allison 1949) However, the converse is not true and most organisms of these phage types do not produce enterotoxin Enterotoxin producing strains do not differ fundamentally from conventional strains of *Staph aureus* in terms of biochemical reactions or in the production of hemolysins coagulase, etc Therefore, identification of toxic strains depends on the direct demonstration of enterotoxin in culture filtrates Few experimental animals are susceptible to enterotoxin the most reliable species for testing are the monkey (*Macaca mulatta*) and man Vomiting can be induced in monkeys by the feeding or the intravenous injection of culture filtrates which contain enterotoxin in both instances there is a latent period of 1½ to 3 hours Several antigenically distinct types of enterotoxin exist A and B are the most common some strains produce both types (Casman *et al* 1963) The enterotoxins are trypsin resistant basic proteins rich in lysine which withstand boiling for 30 minutes Enterotoxin B has a molecular weight of 24 000 and is free of carbohydrate and lipid (Bergdoll *et al* 1959a Hibnick and Bergdoll, 1959) Intravenous injection of 1 mcg /Kg of purified toxin into monkeys produces emesis After an oral or an intravenous dose the animals become refractory to a second dose for a period of several days and this temporary resistance is specific for each antigenic type (Sugiyama *et al* 1962) Following repeated administration of enterotoxin a more lasting resistance develops which may represent true humoral immunity specific antibodies are known to block completely the effects of enterotoxin (Bergdoll *et al* 1959b) Enterotoxin is pyrogenic and its emetic action is enhanced by the prior administration of Thorotrast (Sugiyama *et al* 1963) The site of action of enterotoxin is not certain but the weight of evidence indicates that its effects are mediated by peripheral and/or central neurons rather than through a direct toxic action on the intestine (Clark *et al* 1962)

Other Substances Most strains of *Staph aureus* produce a number of enzymes capable of hydrolyzing substances in mammalian tissues or fluids These include nucleases (Cunningham *et al* 1960 Alexander *et al* 1961) proteases (Lack and Wailing 1954),

Dissemination from cutaneous lesions occurs by extension or embolization of infected thrombi and fortunately is rare Particularly dangerous are furuncles on the upper lip or in the nares because of the direct connection of the rich venous plexuses with the cavernous sinus Retrograde extension from such lesions is a common cause of cavernous sinus thrombosis Hematogenous spread of *Staph aureus* may lead to visceral abscess formation particularly in the kidney though indeed any organ may be involved

Acute hematogenous osteomyelitis a disease of young persons is most often caused by *Staph aureus* The incidence has decreased markedly during the antibiotic era Osteomyelitis presents with acute pain tenderness and swelling over the metaphysis of the long bones Early in the course roentgenograms of the bone are normal but then areas of medullary necrosis appear together with marked osteoblastic and osteoplastic reaction The organism can be recovered either from the lesion itself the periosteum or the overlying subcutaneous tissue Necrotic bone (sequestrum) may separate from viable bone and serve as a nidus for continued bacterial growth

Blood borne *Staph aureus* can induce a lesion on a heart valve which is congenitally deformed one previously damaged by rheumatic fever or occasionally on a normal valve The clinical outlook is grave and the rapid downhill course with valve destruction and metastatic abscess formation constitutes the most common form of acute bacterial endocarditis

Staphylococcal bacteremia is a state characterized by the almost constant presence of large numbers of *Staph aureus* in the blood stream Metastatic abscesses are numerous and each in turn may seed the bloodstream and continue the cycle The patient is acutely ill febrile and exhibits profound toxemia This syndrome was almost uniformly fatal before the introduction of antibiotic therapy unfortunately the mortality is still high (30 to 50%) Less hectic and more chronic staphylococcal bacteremia is also encountered and the source of seeding may not be apparent

Staphylococcal pneumonia in adults is almost invariably preceded by viral influenza and is one of the major causes of death during influenza epidemics and pandemics Patchy bronchopneumonia rather than lobar pneumonia is usual and the necrotizing lesions often progress to cavitary abscesses Empyema is common The onset is acute with high fever cough productive of purulent pinkish sputum and cyanosis fatalities are frequent *Staph aureus* pneumonia in children may occur as a complication of measles or whooping cough as well as influenza Recurrent bronchopneumonia is also a serious problem in children with cystic fibrosis In addition what appears to be primary staphylococcal pneumonia with extensive necrosis of pulmonary tissue is seen in infants particularly those under 1 year of age Empyema pneumatoceles and/or pyopneumothorax occur in more than 50 per cent of cases Cutaneous lesions in infants are less well localized than in adults and *Staph aureus* is a major cause of impetigo contagiosa *Staph aureus* is also one of the most common causative agents of neonatal meningitis

Staphylococcal pseudomembranous enterocolitis is characterized by copious diarrhea with attendant symptoms and signs of dehydration fever nausea abdominal pain and vomiting If the dehydration is extreme shock ensues Large numbers of *Staph aureus* are present in the diarrheal stools but even in their absence or in the presence of only low numbers of *Staph aureus* some workers feel that the organism has an etiologic role Many of the strains isolated produce both enterotoxin A and B (Warren *et al* 1963) This disease was clearly recognized before the antimicrobial era but became more frequent when persons were given antimicrobials which affected indigenous intestinal flora but not *Staph aureus*

One of the most troublesome features of invasive staphylococcal disease is the tendency for recurrence in the face of what appears to be an effective cure Osteomyelitis for example may recur as long as 20 years after the initial episode Exacerbations of disease generally are due to the same strain that caused the initial lesion It is believed the recrudescence is due to multiplication of small numbers of organisms persisters localized in necrotic foci or small abscesses that are protected from the host s cellular and humoral defense mechanisms as well as

of the hospital strains is enhanced in patients treated with antibiotics to which the hospital strain is insensitive (Knight *et al*, 1958) As with newborns the most important route of spread is probably direct contact but airborne dissemination and contamination of bed clothing may also play a role (Hare, 1963)

Outbreaks of *Staph aureus* disease occur in adult medical and surgical wards as well as in newborn nurseries The persons most susceptible are those who have undergone major operative procedures and those with severe underlying disorders including disseminated malignancy or leukemia, diabetes hyperadrenalcorticism agammaglobulinemia aplastic anemia or agranulocytosis and viral influenza (Nahmias and Eickhoff 1961)

The finding of asymptomatic persons who carry epidemic strains of *Staph aureus* has led to the controversial concept of the dangerous carrier However disease is not exclusively due to these organisms and many persons carry the epidemic strains without apparent harm to themselves or their associates Nevertheless the existence of strains with epidemiologic virulence calls for alertness to the possibility of outbreaks of serious disease

Both nasal and skin carriage of *Staph aureus* often are eliminated temporarily by topical application of antibiotics to the anterior nares This suggests that in many instances skin isolates represent transient contamination by organisms in the nose The carrier state can also be eradicated by systemic antimicrobial therapy but organisms of the original phage type often reappear 1 to 4 weeks after the cessation of treatment The mechanisms involved in the persistence of organisms are unknown

In view of the extremely high rate of carriage in human populations it is clear that the primary reservoir of *Staph aureus* is man but many domestic animals including dogs can be asymptomatic carriers of strains associated with human disease In addition strains implicated in diseases of animals such as those producing bovine mastitis may also produce disease in man

Diseases of Man

The characteristic lesion produced in man by *Staph aureus* is the abscess and the most frequent area of involvement is the skin Large numbers of granulocytes rapidly migrate to the site of bacterial localization and there is exudation of plasma components as well If the cocci are not ingested and destroyed during the initial inflammatory response more phagocytic cells and fluid accumulate In the fully developed lesion there is a central necrotic core filled with dead leukocytes and bacteria which is demarcated from surrounding tissue by a fibroblastic wall containing viable cocci and phagocytic cells As the necrotic material increases and liquefies the tension within the abscess rises accompanied by marked local pain and tenderness the abscess becomes frankly fluctuant and there is thinning of the overlying skin In the absence of therapy the abscess spontaneously bursts drains and heals Cellulitis and lymphadenitis occur if the lesion is not efficiently walled off Constitutional symptoms do not accompany small abscesses but with severe, deep seated lesions there is fever rapid pulse and a polymorphonuclear leukocytosis

Minor cutaneous abscesses are termed pustules and larger ones furuncles (boils) A more serious skin lesion is the carbuncle which is a laterally burrowing interconnected lesion usually occurring in the thick collagenous tissue of the back of the neck, that has multiple channels of egress to the skin Approximately 80 per cent of persons will incur one or more episodes of superficial lesions during their lifetime and the yearly incidence is somewhere between 2 and 10 per cent of the population Fortunately the lesions are usually self limited and not of serious consequence Nevertheless local abscesses, such as infected hangnails (paronychia) prevent normal function of manual tasks and may mean temporary economic disability Moreover 20 per cent of patients with one episode have one or more recurrences during the ensuing year and the risk of disease for members of the family is 4 times greater than in the general population (Kay 1962) A small number of patients have chronic recurrent furunculosis lasting over several months or even years due to the same phage type of *Staph aureus* It is impossible to predict which patients will fall into this category nor is it known why the episodes suddenly cease

that of mice Animals inoculated intravenously with 10^9 to 10^{10} organisms usually die within 24 hours whereas after an inoculum of 10^8 organisms the deaths occur after several days and suppurative renal lesions are the most striking finding (Cowan 1939b Stamp 1961 Li and Kapral 1962)

It is clear from the above that the experimental animals commonly used in the study of staphylococcal disease are markedly resistant to *Staph aureus* Other animals such as guinea pigs afford no particular advantage and although infection of the chick embryo has been studied this model is clearly unrelated to human disease The chinchilla is uniquely susceptible to staphylococcal enterocolitis (Wood *et al* 1956)

Many artifices have been designed to enhance the pathogenicity of *Staph aureus* in experimental animals The lethal intraperitoneal dose in mice is decreased markedly by suspending the organisms in mucin cutaneous lesions are more readily induced after tissue injury (Goshi *et al* 1961) systemic *Staph aureus* disease is enhanced by the administration of a variety of substances including thyroxine and dinitrophenol and animals are more susceptible during acute starvation (Smith and Dubos 1956b c) Resistance to staphylococcal disease is also increased by many nonspecific factors particularly after heterologous immunization (Cowan 1939b)

A few experimental studies have been performed in man Elek and Conen (1957) showed that the skin of normal humans is highly resistant to induced staphylococcal disease Formation of self limited pustules occurs only when more than 5×10^6 cocci are injected irrespective of whether the organism is isolated from normal flora or from lesions In surgical patients stitch abscesses are the most common form of staphylococcal disease the minimum pus forming dose in normal skin can be reduced to as few as 100 cocci if the organisms are impregnated on a silk suture tied through the skin The suture technic for enhancing *Staph aureus* infection is also applicable to experimental animals (James and MacLeod, 1961)

It is difficult to establish the carrier state for prolonged time periods in experimental animals but some information on the phenomenon of persistence has been obtained Following intracerebral or subcutaneous injection of *Staph aureus* organisms can be recovered for several weeks in the absence of a discernible lesion (Fisher 1962 Fisher and Robson 1963) Moreover despite prolonged intensive streptomycin therapy a few surviving fully streptomycin-susceptible *Staph aureus* cells can be found in the kidneys of intravenously injected mice for long periods of time (McCune *et al* 1956) Guinea pigs exposed to tetracycline resistant *Staph aureus* by aerosol retain culturable organisms in their nares for only a few days but the organisms can be evoked by the administration of tetracycline as long as 6 months after initial exposure (Simon 1963)

Pathogenicity and Virulence

The roles in the production of disease played by the many toxins and enzymes synthesized by *Staph aureus* are uncertain Local or systemic injection of culture filtrates containing α toxin into susceptible animals causes tissue necrosis or death (Blair 1958) but preformed toxin present in the usual bacterial inoculum apparently plays no role in the development of lesions Organisms suspended in saline are no less virulent than those suspended in culture medium containing α toxin (Elek and Conen 1957) The small role of α-toxin in the development of progressive lesions is further demonstrated by the general failure of active or passive immunization against α toxin to protect against the development of progressive disease (Smith 1937 Elek, 1959 Foster 1963) However rabbits injected with toxoid are protected against pustule formation in traumatized skin, although not in normal skin (Goshi *et al* 1961b)

Under certain circumstances α toxin seems clearly to be of importance For example immunization with toxoid prevents acute death in experimental animals given large intravenous inocula of *Staph aureus* In contrast, such immunization does not affect the outcome of rapidly fatal intraperitoneal infections associated with the finding of large amounts of α toxin in the peritoneal fluid (Koenig *et al* 1962) The paradox may re

from antimicrobial agents There is also speculation that *Staph aureus* may persist in an altered state such as the G form which is not readily cultured and which resists a variety of bactericidal substances

Food poisoning due to *Staph aureus* is due to ingestion of preformed enterotoxin The symptoms usually begin 3 hours after ingestion, but the time of onset ranges from 1 to 6 hours The heralding sign is increased salivation, followed by nausea, vomiting abdominal pain and watery diarrhea Recovery is generally within 24 hours and death occurs only when dehydration is excessive, particularly in infants or the debilitated

Diseases of Animals

Staph aureus is found in lesions in a variety of wild and domestic animals and birds but the specific role of the organism is difficult to define since other microorganisms are often present However disease in sheep and cows particularly bovine mastitis may be due solely to *Staph aureus* approximately 70 per cent of dairy herds in the United States have staphylococcal mastitis (Courter and Galton 1962) The strains isolated from animals are more likely to be of phage type 42D and to produce β hemolysin than human strains However strains of a variety of phage types including 80/81 are also found Many different strains of *Staph aureus* can also be carried by animals free of disease

The presence of *Staph aureus* in domestic animals may affect man Enterotoxin producing strains can incite bovine mastitis and raw milk and its products have been responsible for several outbreaks of food poisoning *Staph aureus* carriage and/or invasive disease can also be exchanged between man and domestic animals The use of antibiotics in animal food like the use of antibiotics in human populations is accompanied by an increase in the number of antibiotic resistant strains which are carried Thus 93 per cent of *Staph aureus* strains isolated from pigs fed tetracycline were resistant to the drug whereas only 5 per cent of strains obtained from animals not fed the antibiotic were resistant (Smith and Crabb 1960)

Experimental Infection

Most laboratory animals are relatively resistent to infection with *Staph aureus* and none of the experimental models is an accurate reproduction of human disease Intracutaneous inoculation of as many as 10^7 organisms in the mouse or the rabbit produces only small self limited necropurulent lesions (Johnson *et al* 1961, Fisher 1962) Larger doses in the rabbit cause spreading erythematous necrotic lesions Intramuscular injection of *Staph aureus* in mice induces local edema and infiltration with inflammatory cells The intensity of the reaction as determined by the degree of swelling is sometimes used as a criterion of the virulence of a particular strain (Selbie and Simon 1952)

The dynamics of intraperitoneal infection in mice have been studied extensively Quite large inocula of most strains 5×10^8 to 5×10^9 organisms are required to produce lethal disease In most cases death occurs within 24 hours and is associated with the production of large amounts of α toxin in vivo (Cohn 1962, Koenig *et al*, 1962)

Intravenous injection of approximately 10^8 to 10^9 viable units kills mice within 24 hours The acute deaths are usually ascribed to the production of α toxin in vivo When between 10^7 and 10^8 organisms are inoculated delayed deaths occur The injected cocci are cleared rapidly from the blood stream and can be recovered primarily from the major organs of the reticuloendothelial system the spleen and the liver (Smith and Dubos 1956a Fisher 1962) Lesser numbers are present in the lungs and the kidneys The titers of organisms in the spleen and the liver gradually decrease until 2 weeks later virtually no cocci can be recovered whereas the number of organisms in the lungs remains relatively constant However there is a gradual increase in the bacterial population of the kidneys which may reach 10^9 to 10^{10} staphylococci and renal abscesses are found Quantitative studies indicate that at least 10^4 organisms must be extracted by the kidneys after challenge before progressive fatal lesions develop the anatomic site of multiplication is the cortex The fate of rabbits receiving intravenous *Staph aureus* is similar to

termining the outcome of encounters with *Staph aureus*

Studies on the interaction between *Staph aureus* and phagocytic cells reveal that both heat stable and heat labile factors are required for efficient ingestion (Cohn and Morse 1959 Rogers and Melly 1962) The heat stable substance is specific antibody whereas the labile factor is presumed to be a component of the complement system Normal rabbit serum does not contain *Staph aureus* opsonizing antibody and the organisms are not ingested in vitro by either polymorphonuclear leukocytes or macrophages unless antiserum is added (Cohn and Morse 1959 Mackaness 1960) However phagocytosis of *Staph aureus* by fixed or circulating cells in the intact rabbit may not depend on opsonic antibody since very large inocula are required to produce disease It is known that *Staph aureus* is ingested in the absence of antibody by the process of surface phagocytosis *Staph aureus* is readily ingested by human leukocytes suspended in human serum which unlike rabbit serum normally contains opsonizing antibodies

The dynamics of the phagocytosis of *Staph aureus* in vivo have been studied in the peritoneal cavity of the mouse where ingestion of the organism by mononuclear and polymorphonuclear leukocytes has been shown to be efficient It is not certain whether normal mouse sera contain opsonizing antibodies

Once ingested more than 95 per cent of *Staph aureus* cells are killed rapidly within human and rabbit leukocytes in vitro and within mouse leukocytes in vivo (Cohn and Morse 1959 Mackaness 1960 Rogers and Melly 1960 Cohn 1962) It is uncertain whether the existence of small numbers of viable intraleukocytic organisms is of significance in the production or the persistence of *Staph aureus* disease The mechanism of killing within granulocytes is probably related to the presence within these cells of the bactericidal basic protein phagocytin (Hirsch 1960) since *Staph aureus* is resistant to lysozyme as well as to the acid pH of the intraleukocytic environment

Apparent defects in phagocytosis of *Staph aureus* are observed when an inoculum is manifestly larger than the number of cells mobilized to the inflammatory site or when emigration of phagocytes is retarded by vascular compromise or by the administration of adrenal cortical hormones Under these circumstances *Staph aureus* multiplies extracellularly at a rapid rate producing a variety of toxins and enzymes and the lesions may become progressive Phagocytosis of *Staph aureus* by mouse peritoneal cells can be impaired by suspending the inoculum in mucin but in man the induction of cutaneous lesions is not affected

The opsonic determinants of conventional strains of *Staph aureus* are not completely known Some workers suggest that antibodies against Polysaccharide A are necessary for phagocytosis to occur (Mudd *et al* 1963) In the case of the unique mucoid strains such as the Smith strain the capsular material is an important determinant of phagocytosis (Morse 1962a) Absorption of antiserum by the isolated capsular antigen removes opsonizing antibodies and immunization of mice with this antigen produces protection against an intraperitoneal challenge with the mucoid strains suspended in mucin Immunization with the antigen does not protect against challenge with conventional strains in mucin or the Smith strain suspended in saline (Morse 1962a Fisher *et al* 1963) Strains of the Smith type are encountered infrequently are readily phagocytized by human leukocytes and apparently are not of exceptional virulence for man

There have been many attempts to induce antibacterial immunity to conventional strains of *Staph aureus* in experimental animals In the case of *Staph aureus* antibacterial immunity implies the production of factors which increase phagocytosis of the organism since serum bactericidal or bacteriostatic antibodies are nonexistent Experimental studies are plagued by two major problems Most animals including man have a high degree of resistance to staphylococcal disease and protective effects which are observed are often of doubtful significance Secondly resistance to *Staph aureus* in both man and experimental animals often can be increased by immunization with heterologous bacteria or bacterial products (Cowan 1939b)

Despite these inherent difficulties available evidence suggests that specific antibacterial immunity to conventional strains of

flect the production of α toxin in the peritoneal cavity in amounts exceeding the binding capacity of antitoxin It is of interest in this regard that α toxin production in vivo is greater than that in vitro (Gladstone and Glencross 1960 Cohn 1962)

The role of α toxin in human staphylococcal disease is not clear It does not affect human erythrocytes and leukocytes but is capable of damaging skin The intracutaneous injection of an amount of preformed toxin sufficient to produce large areas of redness and swelling does not potentiate the ability of a given inoculum to produce a pyogenic lesion (Elek and Conen 1957) Moreover, approximately 4 per cent of strains isolated from human lesions do not manufacture α toxin in vitro (Lack and Wailing 1954) On the other hand Kleiger and Blair (1940) have pointed out that the symptoms of acute staphylococcal toxemia mimic the manifestations which follow the intravenous injection of α toxin into experimental animals and it is likely that α toxin was responsible for some of the deaths in the Bundaberg disaster

Neither β hemolysin nor δ hemolysin have been shown to be responsible for particular manifestations or the development of human disease, but it is noteworthy that δ hemolysin is toxic for human leukocytes

Coagulase has also been implicated as a factor in pathogenicity It was originally suggested that the deposition of fibrin about the organisms due to either free or bound coagulase might inhibit the ability of phagocytic cells to engulf *Staph aureus* (Hale and Smith 1945) careful studies fail to support this notion (Rogers and Tompsett 1952) Although injection of large amounts of free coagulase produces widespread clotting in vivo extensive intravascular clotting does not accompany severe or fatal staphylococcal disease (Fisher 1936) Strains of *Staph aureus* varying in ability to clot guinea pig plasma do not vary in capacity to produce disease in these animals (Foster 1962) Moreover laboratory derived mutants lacking free and bound coagulase are as pathogenic for rabbits as the parent strain (Li and Kapral 1962) Coagulase may actually act in favor of the host by localizing lesions through the deposition of a fibrin barrier and it is of interest that infants and children who tend to have more spreading lesions have lower levels of coagulase reacting factor than adults (Rammelkamp and Lebovitz 1956) On the other hand mice and fowl which are deficient in CRF, are very resistant to *Staph aureus* disease Specific protection by immunization with preparations rich in Type I but not Type III coagulase in rabbits has been reported (Lominski *et al*, 1962), but in other experiments (Fisher, 1962) protection was not correlated with titers of circulating anticoagulase

The P-V leukocidin destroys human leukocytes and it is possible that this effect in vivo aids the initiation and the progression of disease There is an inverse correlation between the level of cord blood antileukocidin and the incidence of staphylococcal disease in the newborn (Johanovsky, 1959 Banfer 1962) Moreover immunization of pregnant women with leukocidin rich toxoid decreases the incidence of disease in both the newborn and mothers Whether these observations reflect correlative or nonspecific factors awaits the results of intensive studies now being pursued

Other potentially injurious enzymatic products such as hyaluronidase lipase etc have been implicated as determinants of pathogenicity but they do not appear to be primary factors (Elek 1959) Strains possessing all these factors may be found in healthy carriers but strains lacking one or more of the enzymes or toxins mentioned (with the exception of free coagulase which defines the species) have been isolated from human lesions

The ability of a microorganism to survive and multiply in the host can be as important for pathogenicity as the elaboration of toxic substances *Staph aureus* is capable of surviving environmental circumstances inimical to other microorganisms it is unusually resistant to acid mercuric ions heat, hypertonic sodium chloride phenol and drying *Staph aureus* also resists the action of serum bactericidins most strains grow readily in broth containing serum Other body fluids which contain fatty acids lethal for many bacteria do not inactivate *Staph aureus* and the majority of *Staph aureus* strains are also not susceptible to killing by lysozyme

The ability or the inability of host cellular elements to ingest and destroy microorganisms probably plays a central role in de

form free coagulase but the converse is not true Therefore strains that are negative by slide test which otherwise resemble *Staph aureus* should be tested for free coagulase

A variety of differential and selective media are used for the separation and the identification of *Staph aureus* Mannitol fermentation is demonstrated by an appropriate indicator in media containing the polyol free phenolphthalein is liberated by *Staph aureus* phosphatase in phenolphthalein phosphate agar (Barber and Kuper 1951) tellurite is reduced and the organism grows as black colonies on tellurite glycine agar (Zebovitz *et al* 1955) and opacity is produced on solid media containing egg yolk by the action of lipases (Graber *et al* 1958) Selective media incorporate factors such as mercuric ions which are inimical to the growth of other microorganisms (Moore 1960) Most strains of *Staph aureus* grow readily in high salt concentrations Solid nutrient media containing 7 5 per cent sodium chloride are the most useful of the selective media None of the differential media replaces the coagulase test for identification of *Staph aureus* and the use of selective media excludes the growth of other microorganisms which may be of clinical significance For these reasons these media are more useful in epidemiologic studies than in routine laboratory procedures

Susceptibility of a micrococcus to *Staph aureus* bacteriophage clearly identifies it as a member of the species but bacteriophage typing is an epidemiologic rather than a diagnostic tool Determination of antibiotic sensitivity is also more important for clinical and epidemiologic purposes than for diagnosis Epidemic strains generally display a high degree of multiple antibiotic resistance However in the laboratory these organisms can not be differentiated from other *Staph aureus* strains

The physician often asks if a *Staph aureus* isolated from a lesion or from body fluid is of etiologic significance or merely a contaminant The laboratory cannot answer the question In view of the widespread environmental distribution of *Staph aureus* each specimen must be obtained with meticulous precaution to avoid extraneous contamination

Since direct tests for the presence of enterotoxin by feeding of material to monkeys or man is impractical the finding of large numbers of culturable *Staph aureus* in suspected food is presumptive evidence that the organism is the responsible agent in cases of food poisoning However food which has been contaminated and then heated will yield no culturable organisms though the enterotoxin remains active

Treatment and Control

Treatment Most instances of staphylococcal disease are relatively minor cutaneous lesions pustules and furuncles The basic principle of therapy of these lesions is to promote adequate drainage Spontaneous drainage is facilitated by the application of moist hot compresses surgical incision may be necessary but is performed only when the lesion is fluctuant. Systemic antibiotic therapy is not generally warranted Skin care with germicidal baths lessens contamination and decreases the likelihood of auto infection The patient must be warned against manipulation of the lesions to prevent hematogenous spread Carbuncles because of their burrowing characteristic generally do not drain adequately and often both antimicrobial therapy and surgical drainage are required

Serious staphylococcal disease—bacteremia endocarditis pneumonia meningitis acute osteomyelitis etc.—calls for the prompt administration of systemic antimicrobial therapy in large doses and therapy often must be continued for a prolonged time to effect cure The surgical removal or drainage of suppurative foci is of great importance in the outcome of these conditions

When penicillin was first introduced 85 to 90 per cent of *Staph aureus* strains were sensitive to the antibiotic Although there is considerable variation more than 80 per cent of strains now responsible for serious hospital acquired staphylococcal disease are penicillin resistant and 20 to 40 per cent of community strains also are not susceptible In addition hospital strains are frequently resistant to other antibiotics such as tetracycline about 50 per cent chloramphenicol about 40 per cent and erythromycin about 40 per cent (Barber and Burston 1955 Rogers 1956 Finland *et al* 1960 Petersdorf *et al* 1960 Cohen *et al* 1962 Cheatle

Staph aureus can be induced in mice and rabbits after administration of cells or cell fractions (Stamp, 1961 Fisher, 1962 Koenig *et al*, 1962 Ekstedt, 1963) In most instances the degree of protection is small and incomplete Passive administration of anti bacterial serum similarly produces partial protection against experimental disease

The importance of allergy to *Staph aureus* in pathogenesis of disease is uncertain but Johanovsky (1958) and Johnson *et al* (1961) have indicated that delayed hyper sensitivity to staphylococcal components in creases susceptibility to experimental disease

As previously stated some strains of *Staph aureus* are epidemiologically more virulent than others but attempts to eluci date the specific factors involved have been unsuccessful and these strains do not induce experimental disease more readily than others

It is obvious that orthodox approaches have not provided a thesis that satisfactorily explains the induction or the development of progressive staphylococcal disease This is particularly true in man in whom the situa tion is compounded by the frequent occur rence of apparently fully pathogenic strains in the absence of illness and the presence in the sera of most normal adults of antibodies to many *Staph aureus* components Varia tions in serum titer of a variety of these anti bodies with the possible exception of anti human leukocidin are not closely correlated with disease One must conclude that in man *invasion of tissues by Staph aureus is* pre vented in most instances by the rapid mobili zation of natural host defense mechanisms reinforced by specific antibodies In the face of local or systemic abnormalities or in the case of the newborn of physiologic imma turity the organism multiplies at a rate which surpasses the ability of the host to destroy the inoculum A multiplicity of unknown fac tors—bacterial toxins or enzymes inactiva tion or inaccessibility of antibodies and phag ocytes etc —then may come into play Delineation of these interactions has proved to be extraordinarily difficult

Persistence of organisms is a phenomenon which relates to pathogenicity as well as to healthy carriage Despite prolonged therapy with an effective antimicrobial agent small numbers of organisms are frequently found in necrotic foci In some situations organisms cannot be cultured and yet disease due to the same phage type of *Staph aureus* recurs after a variable time period It is unknown whether the organisms exist in a site inac cessible to antimicrobials or cultural technics are inadequate or the cocci are in an altered form

Diagnosis

The presence of typical irregular clusters of gram positive cocci in purulent material suggests the presence of staphylococci or other micrococci Precise identification of *Staph aureus* requires laboratory isolation Hemolysis and golden yellow pigmentation of colonies of gram positive cocci in charac teristic aggregation point to the diagnosis as does the ability of the organism to ferment mannitol However, *Staph aureus* strains differ in the types of hemolysins produced and certain strains are nonhemolytic Fur thermore pigmentation as well as fermenta tive capacities vary At the same time other micrococci are hemolytic and can form orange-colored colonies which are difficult to distinguish from those of *Staph aureus*

By definition a strain which produces free coagulase is *Staph aureus* Strains isolated from clinical material that do not produce free coagulase are extremely rare The test for free coagulase is performed by adding 0 5 ml of a broth culture or a loopful of agar growth to 0 5 ml of a 1 5 dilution of citrated *human or rabbit plasma in* a serologic test tube The mixture is incubated at 37° C Definite clot formation usually occurs within 3 hours but may not take place for 18 hours Each plasma lot should be tested with a known coagulase positive strain to ensure that inhibitors or coagulase antibodies are not blocking the reaction

Because free and bound coagulase gen erally are found together the simple and con venient slide test for bound coagulase is often used as a routine screening procedure (Cadness Graves *et al* 1943) A bacterial suspension is mixed with a drop of plasma or fibrinogen solution on a microscope slide in a positive reaction clumping of the ba teria occurs within 30 seconds Virtually all strains that produce bound coagulase also

multiply readily should be kept refrigerated until use Many different foods have been found to be the source of food poisoning out breaks but bakery products particularly those with cream fillings gravies and certain meats are implicated most frequently There is no external evidence such as a change in the taste or the smell of food that indicates contamination with *Staph aureus* Entero toxin is heat stable and therefore heating of contaminated food will not destroy the toxin though viable organisms are killed

Immunity in Man

Sera of most normal adults contain anti bodies to a variety of components and prod ucts of *Staph aureus* including α toxin co agulase human leukocidin hyaluronidase staphylokinase Polysaccharide A and the agglutinogen Antigen A In addition human gamma globulin protects mice against in vasive staphylococcal disease (Fisher 1959) Antibodies to α toxin leukocidin staphy lokinase Antigen A and the mouse protec tive factor are known to cross the placental barrier Antibody titers in the infant decline during the first few months of life and then rise over the next few years presumably as the result of the antigenic stimulus derived from carriage of *Staph aureus* or minor le sions (Quie and Wannamaker 1964) No correlation between the titer of a particular antibody and resistance or susceptibility to disease has been discovered It is noteworthy that an increase in antibody titer does not occur regularly in patients with disease even when the illness is chronic (Lack and Towers 1962)

Despite the presence of antibodies in nor mal sera and the apparent inability of natu ral infection with *Staph aureus* to induce protection against recurrence there is still interest in active immunization as a way of increasing resistance particularly in patients with recurrent furunculosis Among the ma terials that have been used for immunization are toxoids prepared from culture filtrates rich in α toxin or leukocidin killed *Staph aureus* isolated either from the patient (au togenous vaccine) or from other sources and lysates Reports of successes are approxi mately as numerous as those of failures Some of the successes may be related to non specific factors Studies on active immuniza tion continue in many parts of the world and as the components of the vaccines are eluci dated the materials standardized and spe cific serologic responses measured precise information may be forthcoming

STAPHYLOCOCCUS EPIDERMIDIS

Staph epidermidis (*Staph albus*) resem bles *Staph aureus* closely in microscopic morphology Colonies are almost invariably chalkwhite and zones of clear hemolysis due to ϵ hemolysin are seen on blood agar (Elek and Levy 1950) The organism grows well on most nutrient media biotin is required for aerobic growth and uracil for anaerobic growth (Jones *et al* 1963) Acetoin is formed from glucose and nitrates are re duced to nitrites A variety of sugars are fer mented but unlike *Staph aureus Staph epidermidis* does not ferment mannitol and gelatin is liquefied only at a slow rate The most important feature that differentiates the species is that *Staph epidermidis* strains do not produce coagulase they are often re ferred to as coagulase negative staphylococci Coagulase negative staphylococci are sensi tive to inhibition or killing by a variety of factors in the milieu such as high salt con centration which do not affect *Staph aureus*

The species antigen of *Staph epidermidis* is also a cell wall teichoic acid Polysaccha ride B which has a polyglycerophosphate backbone Monoglucoside units in α linkage which are the antigenic determinants are attached to some of the glycerols whereas others have D alanine residues in labile ester linkage (Morse 1963b) The antigen does not cross react with Polysaccharide A of *Staph aureus* but a common protein antigen in the two species has been reported (Elek 1959)

Staph epidermidis does not produce the extensive complement of toxins and enzymes found in *Staph aureus* and the organism is essentially nonpathogenic in experimental animals In man *Staph epidermidis* is a part of the normal mucocutaneous flora It pro duces disease less frequently than *Staph aureus* but may be responsible for minor cu taneous lesions such as infected acne and small pustules particularly stitch abscesses Serious disease including endocarditis and

1962) The recent synthesis of penicillins insusceptible to *Staph aureus* penicillinase, such as methicillin has materially aided therapy of disease due to penicillinase producing strains of *Staph aureus* (Batchelor *et al*, 1963)

Acute staphylococcal pneumonia or bacteremia is often a medical emergency, and penicillin plus methicillin is given until the sensitivity of the organism is determined Vancomycin is a useful drug in treating patients allergic to penicillin and some physicians utilize bacitracin and kanamycin despite their inherent toxicity *Staph aureus* strains that are resistant to methicillin have now been isolated and no doubt will increase in frequency The methicillin-resistant strains are fully capable of producing disease and the problem of antimicrobial therapy of *Staph aureus* disease is therefore by no means solved (Chabbert and Baudens 1962 Jevons *et al* 1962 Stewart and Holt 1963)

Other antibiotics such as erythromycin tetracycline and chloramphenicol are not indicated for the primary treatment of severe staphylococcal disease but may be of use in treating minor lesions and occasionally in combined therapy of disease which does not respond to the administration of a single antimicrobial agent

Passive administration of anti α toxin is not generally employed in the management of severe staphylococcal disease nor has the use of human gamma globulin as a specific therapeutic measure been rewarding. Both local and systemic bacteriophage therapy have been tried also without significant success

Control There is no practical way of removing *Staph aureus* from its widespread and usually benign association with man Efforts are directed toward the prevention and the control of disease in hospitals where contact occurs between susceptible persons and apparently more virulent strains Hospitals tend to have their own unique staphylococcal problem and the uncertainties regarding the spread and the acquisition of *Staph aureus* prevent the delineation of firm rules Certain general principles are of importance Persons with staphylococcal lesions disseminate large numbers of organisms and they should be segregated from adult susceptibles or newborns Similarly, ward personnel with open lesions are not allowed to perform their usual duties Highly susceptible individuals, such as those with agranulocytosis are protected from other patients and personnel who are carriers Especially to be avoided is the indiscriminate use of antimicrobials which may lead to the acquisition of resistant strains by the patient and the prevalence of such strains within an institution Finally all minor or major surgical procedures and wound care should be performed with maximal asepsis

Questions regarding the disposition of asymptomatic carriers of an epidemic strain are difficult to answer except in specific situations It is advisable that each institution establish a surveillance committee to evaluate the risks involved and to act promptly if an epidemic occurs Under epidemic conditions a search for the source of infection is initiated and personnel who are carriers of offending strains are removed from the ward and not permitted to return until the carrier state is eliminated (Nahmias and Eickhoff 1961 Williams and Shooter 1963) Nevertheles despite intensive efforts to eliminate carriers and isolate patients closed epidemics are often recurrent, and entire wards have had to be closed

The newborn is particularly susceptible to staphylococcal disease and decreased colonization by hospital strains is achieved by care of the umbilical stump and the skin with germicidal liquid or powder Shinefield and co workers (1963) recently presented a novel way of protecting infants from acquiring epidemic strains A penicillin sensitive strain of *Staph aureus* which does not have epidemiologic virulence is implanted in small numbers in the nares or on the umbilicus soon after birth The carrier state thereby established seems to prevent or retard colonization by epidemic strains during the limited hospital stay of the infant This is an example of a process variously termed interference infection immunity or premunition

Prevention of food poisoning due to *Staph aureus* involves avoidance both of food contamination and bacterial growth Persons with open lesions should not participate in the preparation of food More importantly foodstuffs in which enterotoxinogenic strains

bacteremia, can also occur, particularly in debilitated persons and the mortality is high (16 to 20%) Therapeutic principles for *Staph aureus* disease apply also to *Staph epidermidis*—drainage of abscesses and administration of antimicrobials in severe disease

Many strains of *Staph epidermidis* are resistant to antibiotics In a recent study of 175 clinical isolates most of them from blood cultures 50 per cent were resistant to penicillin and 10 per cent were resistant to methicillin (Kjellander *et al*, 1963) Insusceptibility to penicillin is due both to the production of a penicillinase which like *Staph aureus* penicillinase is a beta lactamase and to a level of inherent resistance (Kjellander and Finland 1963) Many of the strains were also resistant to chloramphenicol tetracycline and erythromycin Thus the antimicrobial therapy of serious disease due to *Staph epidermidis* holds many of the problems found in treating illness caused by *Staph aureus*

OTHER MICROCOCCI

Gaffkya tetragena (M tetragenus) This *species of the genus Gaffkya is distinguished* by the arrangement of cells in packets of fours (tetrads) which are often surrounded by a capsule or pseudocapsule These features are found in material obtained directly from animal tissue or fluids but in artificial culture the characteristics may not be apparent *Gaffkya tetragena* is slower growing *than the staphylococci It is a facultative* anaerobe On agar, the colonies are white-to gray moist gleaming and viscid A variety of sugars are fermented but not mannitol Gelatin is not liquefied Coagulase is not formed by *Gaffkya tetragena* nor by the other micrococci The organism can be isolated from the normal upper respiratory tract or the skin of man and frequently is found in the sputum of tuberculous patients *Gaffkya tetragena* produces a rapidly fatal septicemia in mice In man either localized or septicemic disease occasionally occurs particularly in persons with lowered general resistance

Sarcina The cocci in this genus tend to divide perpendicularly in 3 planes resulting in the formation of packets of 8 16, 32 or more elements Some species are anaerobic but the species most commonly isolated from the environment of man is the aerobic *Sarcina lutea* *Sarcina lutea* produces sulfur to chrome yellow colonies on agar, and pigment is formed in liquid culture Sugars are not generally fermented Human disease caused by *Sarcina lutea* is extremely rare

The other aerobic species of micrococci which, like staphylococci, grow in irregular masses constitute a heterogeneous group included in the genus *Micrococcus* They are of relatively little importance in human disease

The Meningococci

The meningococci are gram negative cocci, usually occurring in pairs which form non pigmented translucent colonies and ferment dextrose and maltose with production of acid They are aerobic nonsporulating and non motile They are strict parasites of man and are the cause of several types of infections of which the most important are meningo coccemia and meningococcal meningitis The accepted name is *Neisseria meningitidis* al though occasionally used synonyms are *Neis seria intracellularis* and *Diplococcus intra cellularis meningitidis*

HISTORY

Epidemic cerebrospinal meningitis is un doubtedly an ancient disease but its early history remains unclear because of the diffi culty in differentiating it from other syn dromes of a similar nature This confusion is exemplified by some of the names used to describe the disease in the early 19th century viz sinking typhus spotted fever and brain fever According to Hirsch (1886) the disease was first recognized in epidemic form in Geneva Switzerland in 1805 by Vieusseux and 1 year later in the United States at Medfield, Mass where an outbreak was described by Danielson and Mann Dur ing the next 75 years an increasing number of outbreaks of a disease which may be pre sumed to be epidemic cerebrospinal menin gitis on the basis of clinical and epidemiologic data occurred in Western Europe and the United States Military forces particularly those stationed in barracks seemed to be un duly prone to epidemics of the disease By the end of the century outbreaks had been re ported from Asia Africa and Australia as well The isolation and the description of the causative organism *Neisseria meningitidis* from spinal fluid of a clinical case by Weich selbaum in 1887 permitted the diagnosis to be made with certainty Since then extensive outbreaks have occurred in many parts of the world A major epidemic occurred in New York City in 1904 and 1905 During World War I the Allied Forces both in England and on the Continent, suffered from outbreaks of the disease In the United States in recent years it has tended to occur at irregular inter vals There was a severe outbreak in the period of 1928 to 1930 and another during the opening years of World War II 1940 to 1943

With the widespread application of diag nostic laboratory procedures our knowledge of the disease increased rapidly It was recog nized that meningococcal meningitis could occur endemically as well as in the form of epidemics A septicemic form of the disease in which the central nervous system was not involved was recognized and given the name meningococcemia The organism was iso lated from the nasopharynges of a significant number of individuals during the course of routine surveys and based on this evidence

the concept of the healthy carrier developed

Dopter (1909) was the first to recognize the existence of serologically specific types of meningococcus This work was continued and extended by British and French workers during World War I and laid the firm basis for our present system of classification Serum therapy for meningococcal meningitis was introduced by Jochmann in 1906 and its use was firmly established by the work of Flexner (1913) The era of chemotherapy started in 1939 and today this form of treatment has completely displaced serum therapy The outbreaks of epidemic disease which accompanied World War II gave investigators the opportunity to carry out valuable investigations on the epidemiology the therapy and specific prevention of the disease The recent reviews by Branham (1953) by Goeters (1954) and by Scherp (1955) may be consulted for further reference

MORPHOLOGIC AND BIOCHEMICAL CHARACTERISTICS

The meningococci are gram negative nonmotile nonsporulating cocci approximately 0 6 to 0 8 microns in diameter which in body fluids and liquid media at least are often arranged in pairs giving rise to the synonym diplococcus When found in pairs the adjacent sides are usually flattened to produce the typical biscuit or reniform shape Considerable variation occurs in both size and staining properties particularly in older cultures Autolysis is a prominent characteristic of the meningococci and is presumably responsible for the numerous ghost cells seen in older cultures as well as for the marked variations in staining properties The organism is usually described as being nonencapsulated since no capsule has been demonstrated unequivocally by direct capsular stains On the other hand in at least 2 groups of meningococci a capsule may be demonstrated in freshly isolated strains by the application of homologous typing serum

On solid media meningococci give rise to smooth nonpigmented and nonhemolytic colonies Freshly isolated strains produce transparent glistening colonies with a smooth border when grown on a transparent medium The so-called lens effect may be observed in that when distant objects are viewed through the colony they become sharply focused Some strains tend to produce mucoid colonies As the colony ages it tends to become opaque and granular and to lose its smooth border Old laboratory strains frequently give rise to rough colonies

Ever since the publication of Murray s monograph (1929) meningococci have been regarded as highly fastidious organisms which require accessory growth factors such as are present in blood serum and certain vegetable extracts Many media incorporating one or more of these products have been devised for the propagation of these organisms However their definitive growth requirements remain to be determined and more recent work by Frantz (1942) among others suggests that the primary difficulty is not a nutritional deficiency but rather the extreme sensitivity of meningococci to the toxic effects exerted by a variety of amino acids fatty acids and salts The role of animal proteins and vegetable extracts in culture media appears to be one primarily of absorbing toxic substances so as to permit growth rather than the furnishing of any necessary growth requirement An atmosphere containing 5 to 10 per cent carbon dioxide enhances the growth of most strains of the organism

The meningococci grow best at a temperature of 35 to 37° C At temperatures higher or lower than this the amount of growth falls off rapidly The organisms are strict aerobes and no growth takes place under strictly anaerobic conditions Blood agar chocolate agar trypticase soy agar and the starch casein hydrolysate agar of Mueller and Hinton (1941) represent the solid media in common use for the propagation of these organisms Growth in broth (tryptose phosphate veal infusion starch casein hydrolysate) is relatively poor resulting in a granular turbidity and little or no surface growth

The carbohydrate fermentation properties of these organisms are sharply limited Dextrose and maltose are fermented with the production of acid but no gas Lactose sucrose levulose and other sugars are not fermented Indole and hydrogen sulfide are not formed but catalase is present In common with other organisms belonging to the genus *Neisseria* meningococci contain cytochrome

TABLE 1 GROUPING OF MENINGOCOCCI

oxidase which rapidly oxidizes dimethyl- or tetramethyl paraphenylene diamine hydrochloride (McLeod *et al* 1934) The presence of this oxidase cannot be demonstrated in killed organisms It provides a useful means for the provisional differentiation of the members of the genus *Neisseria* from other microbial organisms which with rare exceptions lack this enzyme

As previously mentioned, the possession by meningococcus of an active autolytic enzyme system results in swelling loss of staining properties and in the ultimate disappearance of the cell itself in cultures more than a few hours old This process may be halted by the inactivation of the autolytic enzymes either by heating the culture to 65° C for 30 minutes or by the addition of potassium cyanide or formalin

The resistance of the meningococci to physical and chemical agents is relatively low and these organisms experience considerable difficulty in surviving outside the human body They are quite susceptible to desiccation and are killed by heating to 55° C for 30 minutes or by exposure to any of the common germicides in relatively low dilutions Most strains of meningococci are sensitive to the action of the sulfonamides penicillin and broad spectrum antibiotics such as the members of the tetracycline series Although fresh strains are sensitive to the action of streptomycin highly resistant forms develop rapidly and in some instances streptomycin dependent strains are the end result

ANTIGENIC STRUCTURE

At least 4 broad serologic groups of meningococci have been recognized on the basis of antigenic differences The original classification of Gordon and Murray (1915) has been followed in its general outline but the use of different terminologies by English French and American workers has caused a considerable amount of confusion The subject has been reviewed by Branham (1953 1958) The classification described in Table I follows that recommended by a subcommittee of the Nomenclature Committee of the International Association of Microbiologists in 1950 For clarification the terminology in common use in the United States during the period *1940 to 1955* is set up in parallel together with the original classification of Gordon and Murray

Of the 4 types originally described by Gordon and Murray I corresponds to Group A II to Group B, and IV to Group D It is the general consensus today that their Type III cannot be distinguished from Type I and therefore both are included in Group A Strains falling in this group (A) are the causative agents of the great majority of epidemic outbreaks of the disease Group B has been responsible for the majority of sporadic cases occurring in interepidemic periods Group C originally designated II *alpha* has been isolated chiefly from sporadic cases of the disease Very few strains falling into Group D have been isolated in the United States There is relatively little crossing over between the 4 groups In addition to these a number of nasopharyngeal strains have been isolated which have not been agglutinated by any of the specific antisera These organisms apparently play no significant role in the causation of disease The production of group transformation has been described by Alexander and Redman (1953)

Group A and C strains are better antigens than those belonging to Group B and long courses of immunization are necessary with the latter in order to produce high titered diagnostic antisera Chemical fractionation (Scherp and Rake 1935 Kabat 1943) has revealed 3 types of antigenic substances A nucleoprotein or P substance is found in all meningococci as well as in other *Neisseria* and in Type III pneumococci This material apparently contributes to the toxicity of these organisms A polysaccharide or C substance is also found in other members of the *Neisseria* as well as in certain unrelated or

ganisms A Boivin type toxic glucolipid is present in all meningococci and is closely related to similar antigens found in other *Neisseria* In addition a polysaccharide specific for Group A meningococci has been identified and purified in the form of the sodium salt of a polysaccharide acid Although not a complete antigen in itself it is presumably responsible for the specific serologic reactions given by Group A Among these are included the capsular swelling and the so-called halo reaction This last reaction represents the formation of a ring of precipitate around the individual colonies of the Group A meningococci when they are inoculated into an agar medium containing an excess of specific antibody Similar reactions have been observed with Groups B and C strains when they are brought into contact with specific antisera In the case of Group C meningococci this reaction is due to a capsular polysaccharide haptene which is predominantly a polymer of a sialic acid congener (Watson *et al* 1958) No capsule has been demonstrated in Group B meningococci the specific surface haptene appears to be a noncapsular carbohydrate containing polypeptide In the case of Group A antisera at least there appears to be a close correlation between their antipolysaccharide content and their protective ability After absorption of the antiserum with the specific polysaccharide there remains some residual antibody which affords appreciable protection in mice against experimental meningococcal infections (Kabat *et al* 1945)

Group B meningococci contain a protein fraction which is common to all members of the group and is antigenic In addition there is a carbohydrate polypeptide complex (kappa substance) which although not a complete antigen in itself reacts with Group B specific antibodies

Since the early work of Flexner (1907) investigators have recognized the lethal activity of heat killed or autolyzed cultures of the meningococci The fact that such preparations are markedly toxic for laboratory animals has suggested that an endotoxin released by the autolysis of the bacteria is responsible for many of the signs of the disease The endotoxin appears to be relatively nonspecific antigenic and heat stable presumably it contains both nucleoprotein and glucolipid elements

NATURAL HABITAT AND RANGE OF PATHOGENICITY

The meningococci are strict parasites of man their natural habitat is the nasopharynx of this species Natural infections are found only in man and the organisms have a relatively low virulence for other species Flexner (1907) was able to produce a picture of meningitis in monkeys following the intraspinal inoculation of a relatively large number of organisms As pointed out by Murray (1929) laboratory animals such as mice guinea pigs and rabbits are susceptible to the inoculation of meningococci only when the infecting dose is so large that it approaches the lethal dose of the heat killed organisms However if the organisms are suspended in 2 to 5 per cent hog gastric mucin (Miller 1933) a relatively small number of organisms suffices to initiate a fatal infection The enhancing effect of the mucin is due presumably to the protective effect it exerts against the body s natural defense mechanisms Although this technic has been employed in the determination of antibody levels in sera and of the relative efficacy of drugs this type of infection bears little resemblance to the natural disease as it is seen in man hence its usefulness is limited. Embryonated eggs are susceptible to infection following inoculation of the organisms via the yolk sac route and this technic too has been employed for the assay of antibody levels and the therapeutic efficacy of certain drugs There is a considerable variation in virulence between strains of meningococci Old laboratory strains and those which have gone rough are of relatively low virulence as compared with strains freshly isolated from human beings

PATHOGENESIS

Meningococci gain entrance to the human body via the nasopharynx. After becoming implanted in this area they may set up a localized inflammatory reaction or they may remain completely quiescent giving rise to no signs or symptoms In a relatively small proportion of these infections invasion of the

bloodstream takes place This may remain limited as a simple bacteremia, or as the organisms are disseminated through the body, metastatic lesions may be set up in various sites such as the skin joints, ears lungs and adrenal glands and most important of all the central nervous system Here an inflammatory reaction involving the meninges of both the brain and the spinal cord is the chief finding While it is possible that in some instances organisms spread directly from the nasopharynx into the meninges by penetrating through the cribriform plate it is generally accepted that the central nervous system is invaded from the bloodstream Those factors which govern the ability of the organisms to spread from the nasopharynx into the bloodstream and ultimately to reach the central nervous system in a small percentage of these cases remain undetermined In most infections it appears that the organisms do not progress farther than the nasopharynx

It is not clear what are the mechanisms by which the meningococci give rise to the characteristic pathologic findings Presumably the endotoxic material released from the bacterial cells as a result of the process of autolysis is responsible for the initiation of the process The vascular system appears to be particularly sensitive to the action of this material and hemorrhagic manifestations (perhaps due to a Shwartzmanlike phenomenon) are common in the disease In fulminating meningococcemia this hemorrhagic process is particularly noticeable in the skin and in the adrenal cortex. The so-called Waterhouse Friderichsen syndrome is occasionally associated with massive adrenal hemorrhage but widespread vascular dysfunction causing peripheral pooling of the blood appears to be the usual cause of the profound shock associated with this condition rather than acute adrenal cortical failure

Meningococcal infection of the nasopharynx may set up so mild a reaction in the host that it attracts no notice In other instances an acute inflammatory process may progress to the stage of a purulent rhinitis

Meningococcemia presents the picture of acute sepsis with fever chills malaise and prostration Usually the typical rash can be detected early in the disease This consists of dusky red spots or petechiae of varying sizes up to 15 mm in diameter which involve the skin and the mucous membranes of the body In severe cases the petechiae may assume a purpuric appearance as the result of hemorrhage These may reach a diameter of several centimeters and go on to actual necrosis In mild cases the spots disappear within a few days leaving small brownish areas in their wake histologic examination has revealed that these lesions are due to thrombo-embolic involvement of the capillaries Puncture of the lesion frequently demonstrates the presence of meningococci Fulminant infections often give rise to the Waterhouse Friderichsen syndrome characterized by circulatory collapse and shock Diffuse hemorrhage into and necrosis of the adrenal glands are occasionally found at autopsy but these appear to be associated rather than essential pathologic lesions (Ferguson and Chapman 1948) In the absence of this complication recovery is the general rule if the disease is treated vigorously and promptly

Invasion of the central nervous system is marked by signs and symptoms of meningeal irritation and inflammation Severe headache pain in the posterior aspects of the neck on forward flexion nausea vomiting and often coma are prominent features Physical examination reveals muscular spasm stiff neck exaggerated reflexes and positive Kernig and Brudzinski signs Convulsions and bulging fontanelles are common findings in infants

The meningitis is characterized by an acute inflammatory reaction accompanied by thromboses of the smaller blood vessels and hemorrhage In the later stages marked thickening of the meningeal coverings is a prominent feature as the originally purulent exudate becomes organized Encephalitic involvement is characterized by focal areas of hemorrhage thrombosis and perivascular infiltration

IMMUNITY

The mechanism of recovery from clinically recognizable meningococcal infections has not been determined During the course of the clinical illness antibody formation may be demonstrated by a variety of technics including agglutination mouse protection and bactericidal tests among others The role that this antibody formed during the course of the

illness plays in the recovery of the patient remains uncertain Because of the low morbidity rate which makes it statistically improbable that second attacks will occur and because of the existence of several serologically specific meningococcal groups or types nothing is known concerning the potential immunity conferred by a clinical attack of the disease

There is no reliable method for measuring the susceptibility of an individual to either clinical or subclinical infections with meningococci Man appears to be relatively susceptible to inapparent nasopharyngeal infections with these organisms This is evidenced by the fact that a significant carrier rate of meningococci can be demonstrated in the general population throughout the year Most of these infections are entirely silent although a few may give rise to a local inflammatory process in the nasopharynx On the other hand the resistance of man to clinical infections appears to be relatively high in that cases of meningococcemia and meningococcal meningitis are relatively rare even during epidemic periods It has been shown by Thomas and Dingle (1943) among others that a good proportion of the adult human population possesses bactericidal antibodies against the meningococci which may be demonstrated in the test tube The role played by these protective antibodies in limiting the number and the severity of clinical infections remains undetermined However the erratic results obtained with various strains of meningococci suggest that it does not play a dominant role Presumably these antibodies are formed in most instances as a result of inapparent infections but this theory remains to be proved

Although there is some degree of positive correlation between the presence of group specific antibodies and the protective value of a given serum (Branham 1940) the fact that absorption with the whole homologous organism (as opposed to the specific polysaccharide alone) is necessary for the complete removal of the protective effect of the serum suggests that some other material (antigen or haptene) is playing a significant role in the production of protective antibody Presumably this protective antibody or antibodies exerts its beneficial effect through promoting phagocytosis by a process of opsonization and through enhancing the bacteriolytic process In this last regard it appears that both group specific antibody and complement play significant roles in the mechanism of the process Although numerous attempts have been made to develop a satisfactory process of active immunization the results in terms of protective antibody formation have been inconclusive and in general poor

DIAGNOSIS

The laboratory diagnosis of meningococcal infection is made by the isolation and the identification of the specific organism Blood spinal fluid and nasopharyngeal swabs represent the 3 most important materials to be examined for the presence of these organisms Although the technics required for the isolation and the identification of these organisms are not difficult they do necessitate careful attention to the details of the work Furthermore a thorough knowledge of the pathogenesis of the disease is required in order that cultures may be taken from proper sites at the correct moment

The importance of blood cultures in the diagnosis of meningococcemia is obvious in meningococcal meningitis these are positive in approximately half the cases if they are taken early in the course of the disease Blood taken from the basilic vein is inoculated into both liquid and solid media From 5 to 10 ml of blood is added to 100 ml of tryptose phosphate veal infusion or casein hydrolysate broth Approximately 0 1 ml of blood is spread over the surface of a blood agar chocolate agar or casein hydrolysate plate These are incubated at 35° to 37 C under conditions of increased humidity and carbon dioxide content (5 to 10%) Cultures should be inspected daily for 7 days before being discarded as negative In cases of overwhelming sepsis it is not uncommon to recognize gram negative diplococci in simple blood smears prepared for routine hematologic examination Similarly in such cases where petechiae or a purpuric rash are a prominent feature it is often possible to demonstrate the specific organism in these lesions by means of smear or culture or broth

bloodstream takes place This may remain limited as a simple bacteremia or, as the organisms are disseminated through the body metastatic lesions may be set up in various sites such as the skin, joints, ears lungs and adrenal glands and most important of all, the central nervous system Here an inflammatory reaction involving the meninges of both the brain and the spinal cord is the chief finding While it is possible that in some instances organisms spread directly from the nasopharynx into the meninges by penetrating through the cribriform plate, it is generally accepted that the central nervous system is invaded from the bloodstream Those factors which govern the ability of the organisms to spread from the nasopharynx into the bloodstream and ultimately to reach the central nervous system in a small percentage of these cases remain undetermined In most infections it appears that the organisms do not progress farther than the nasopharynx

It is not clear what are the mechanisms by which the meningococci give rise to the characteristic pathologic findings Presumably the endotoxic material released from the bacterial cells as a result of the process of autolysis is responsible for the initiation of the process The vascular system appears to be particularly sensitive to the action of this material and hemorrhagic manifestations (perhaps due to a Shwartzmanlike phenomenon) are common in the disease In fulminating meningococcemia this hemorrhagic process is particularly noticeable in the skin and in the adrenal cortex The so called Waterhouse Friderichsen syndrome is occasionally associated with massive adrenal hemorrhage but widespread vascular dysfunction causing peripheral pooling of the blood appears to be the usual cause of the profound shock associated with this condition rather than acute adrenal cortical failure

Meningococcal infection of the nasopharynx may set up so mild a reaction in the host that it attracts no notice In other instances an acute inflammatory process may progress to the stage of a purulent rhinitis

Meningococcemia presents the picture of acute sepsis with fever chills malaise and prostration Usually, the typical rash can be detected early in the disease This consists of dusky red spots or petechiae of varying sizes up to 15 mm in diameter which involve the skin and the mucous membranes of the body In severe cases the petechiae may assume a purpuric appearance as the result of hemorrhage These may reach a diameter of several centimeters and go on to actual necrosis In mild cases the spots disappear within a few days leaving small brownish areas in their wake histologic examination has revealed that these lesions are due to thrombo-embolic involvement of the capillaries Puncture of the lesion frequently demonstrates the presence of meningococci Fulminant infections often give rise to the Waterhouse Friderichsen syndrome characterized by circulatory collapse and shock Diffuse hemorrhage into and necrosis of the adrenal glands are occasionally found at autopsy, but these appear to be associated rather than essential pathologic lesions (Ferguson and Chapman 1948) In the absence of this complication recovery is the general rule if the disease is treated vigorously and promptly

Invasion of the central nervous system is marked by signs and symptoms of meningeal irritation and inflammation Severe headache pain in the posterior aspects of the neck on forward flexion nausea vomiting and often coma are prominent features Physical examination reveals muscular spasm stiff neck exaggerated reflexes and positive Kernig and Brudzinski signs Convulsions and bulging fontanelles are common findings in infants

The meningitis is characterized by an acute inflammatory reaction accompanied by thromboses of the smaller blood vessels and hemorrhage In the later stages marked thickening of the meningeal coverings is a prominent feature as the originally purulent exudate becomes organized Encephalitic involvement is characterized by focal areas of hemorrhage thrombosis and perivascular infiltration

IMMUNITY

The mechanism of recovery from clinically recognizable meningococcal infections has not been determined During the course of the clinical illness antibody formation may be demonstrated by a variety of technics including agglutination mouse protection and bactericidal tests among others The role that this antibody formed during the course of the

TABLE 2 DIFFERENTIAL CHARACTERISTICS OF *Neisseriae*

for 2 hours in a water bath before being examined A final confirmatory examination may be carried out after overnight incubation at 4° C

Growth characteristics fermentation reactions and serologic tests serve to differentiate other members of the genus *Neisseria* from the meningococci (Table 2) *Neisseria catarrhalis* and *N sicca* are characterized by their ability to grow at room temperature The latter forms rough dry appearing colonies and both species tend to agglutinate spontaneously in saline or normal horse serum Of the various pigmented species of Neisseria only *N flavescens* appears to be of any importance since it was isolated from a small epidemic of meningitis in Chicago by Branham (1930) The growth characteristics of the gonococcus closely resemble those of the meningococcus As regards biochemical reactions *N catarrhalis* and *N flavescens* fail to ferment dextrose maltose and sucrose and the gonococcus ferments only dextrose On the other hand *N sicca* ferments all 3 sugars Agglutination tests will usually demonstrate the antigenic specificity of these organisms Since all *Neisseria* possess the oxidase which attacks dimethyl or tetramethyl paraphenylene diamine hydrochloride this reaction is of little diagnostic value except in instances of cultures taken from the nasopharynx where it may be helpful in the recognition of organisms presumably falling into the genus *Neisseria*

TREATMENT

Serum therapy was introduced by Jochmann in 1906 and its use on a wide scale was stimulated by the report of Flexner in 1913 With the recognition of serologic groups among the meningococci came the development of polyvalent sera for the treatment of the disease with a concomitant improvement in results Although serum therapy is immunologically sound and the beneficial results obtained unquestioned it has found little use since 1940 because of the superior efficacy and ease of administration of chemotherapeutic agents such as the sulfonamides and penicillin

The extreme sensitivity of meningococci to the sulfonamides in the past has made these the agents of choice in the treatment of

Spinal fluid is collected by lumbar puncture in the 4th lumbar interspace The spinal fluid is permitted to drop directly onto the surface of plates of casein hydrolysate blood agar or chocolate agar medium It is well to inoculate a tube of broth in addition and most authorities recommend the incubation of a few ml of spinal fluid collected in a sterile test tube since on occasion positive results will be obtained in this material on subinoculation when the other cultures remain negative Finally approximately 5 ml is collected for physical examination including cell count and smear and in addition immunologic tests A marked polymorphonuclear pleocytosis is the usual finding The fluid is centrifuged and the sediment stained with methylene blue in order to reveal the typical extracellular or intracellular diplococci It is imperative that this examination be made promptly because of the tendency of these organisms to undergo autolysis In those instances where organisms are found in great numbers the addition of a small amount of specific antiserum may result in the demonstration of capsular swelling and the consequent serologic identification of the causative organism A small amount of the supernatant fluid may be transferred to a small precipitin tube in which it is layered gently over an approximately equal amount of monovalent antimeningococcal serum Frequently a positive precipitin reaction may be obtained in cases of severe infections in which the organism has been demonstrated in the sediment. Occasionally a positive reaction may be obtained even when no organisms are visible in the smear The reaction observed is usually specific for the various serologic groups of meningococci and thus affords a rapid method of diagnosis

Since meningococcal meningitis represents a purulent form of the disease the spinal fluid shows a predominance of polymorphonuclear leukocytes The finding of such a fluid in the course of an epidemic should be taken as presumptive evidence of infection due to the meningococcus until proved otherwise The general inflammatory nature of the meningeal reaction is reflected by the increase of spinal fluid protein and by the abnormal colloidal gold curve If organisms are present in significant numbers, the spinal fluid sugar level is reduced accordingly as in the case of other pyogenic forms of meningitis Nasopharyngeal cultures are of importance since in most cases of meningococcal meningitis and meningococcemia cultures taken from this area yield positive results In such instances the organisms isolated from the blood or the spinal fluid and from the nasopharynx are almost inevitably of the same group The culture is taken by means of a bent wire swab with cotton wool on the end This is inserted carefully behind the uvula and the soft palate so as to avoid contamination from other oral structures and is rubbed gently over the surface of the posterior nasopharynx. Then the swab is drawn over part of a suitable plate and the streaking is completed by means of a wire loop Prompt inoculation and incubation of these plates are of importance however if this is impossible the meningococci may be preserved by inserting the swab into a small amount of sterile horse blood contained in a sterile tube Under these conditions apparently there is no significant diminution in the number of viable organisms over a period of some hours If positive blood and spinal fluid usually yield the organism in pure culture frequently nasopharyngeal cultures give the same results Suspicious colonies and broth cultures may be subcultured for the identification of the specific organism by means of gram stain fermentation tests and serologic typing The morphologic appearance of the meningococcus on smear has been described These organisms usually ferment maltose and dextrose although the reaction may be delayed and somewhat erratic in the case of freshly isolated strains Sucrose is not fermented For serologic identification suspicious colonies are emulsified in small amounts of saline which usually contain 0 1 per cent potassium cyanide to inhibit the autolytic process The addition of group-specific antisera A B or C usually results in the specific identification of the organism by means of the agglutination test Strains isolated from the nasopharynx during interepidemic periods are frequently untypable Error due to nonspecific agglutination should be guarded against by the use of a normal control serum diluted 1 50 and of a saline suspension of the organism The tube agglutination test has been found to yield reliable results the suspension is shaken at room temperature and incubated at 37° C

laboratory methods for the isolation and the identification of the organism have increased our knowledge of the epidemiology of meningococcal infections. Inapparent or subclinical cases far outnumber clinically recognizable cases. "Healthy" carriers are fairly common in both interepidemic and epidemic periods, yet even in the latter relatively few of the "carriers" develop clinically recognizable disease. A positive correlation between the carrier rate and the incidence of clinical cases has long been postulated, but careful analyses carried out in World War II (Pharr and Schoenbach 1944; Aycock and Mueller 1950) have shown that no such relationship exists.

The vast majority of epidemic outbreaks of meningococcal meningitis are due to Group A strains, although small outbreaks due to Group C strains have been reported. Sporadic cases of the clinical disease are usually due to Group B or C strains. Cases due to Group D strains are so rare that the data are inconclusive. These facts are reflected in the carrier rates. In interepidemic periods, Group B strains represent the predominating organism isolated from carriers; in actual fact, Group A strains are marked by their rarity. However, in epidemic periods, strains belonging to this latter group may furnish a significant proportion of the organisms isolated from apparently healthy individuals.

The clinical disease has long been associated with military camps and barracks, and, in these, recruits have appeared to suffer far more than seasoned troops. Immunologic inexperience and susceptibility to excessive fatigue consequent upon the "hardening" process of the raw recruit have been given as factors influencing this difference of incidence, but convincing evidence is lacking. No doubt overcrowding, a situation often found among military and civilian groups during wartime conditions, favors the spread of the organism from one individual to another (Hirsch 1886). However, even during the course of an epidemic in a closed group, it is difficult to find evidence of spread from one *clinical* case to another. The epidemiology of meningococcemia and meningococcal meningitis will not be clear until some understanding and recognition are obtained of those factors in the host which permit or favor the development of the clinically innocuous carrier state into a full-blown case of a dramatic and dangerous disease.

PREVENTION

The extreme degree of sensitivity of the meningococci to the action of the sulfonamide compounds has rendered chemoprophylaxis the most effective method of preventing clinical cases of meningococcal infection in the past. The efficacy of small doses of sulfadiazine in clearing the carrier state was demonstrated early in World War II, and the knowledge was quickly applied to the institution of chemoprophylactic measures on a large scale, with gratifying results. While small doses resulted in the prompt disappearance of meningococci from the nasopharynx, there was a general tendency for the organisms to reappear after an interval of a few days. Larger prophylactic doses resulted in the disappearance of the organisms for appreciably longer period of time. The results of continuous prophylaxis (1 Gm of sulfadiazine per day over a period of months) may be illustrated by the experience of United States naval recruits in World War II. Although the primary object of chemoprophylaxis was the reduction of infections due to beta hemolytic streptococci, the virtual elimination of meningococcal meningitis in the recruits during an epidemic period was the most impressive result.

In the light of these results it seems wise to give close contacts of frank cases of meningococcal disease brief courses of chemoprophylaxis with sulfisoxazole or other soluble sulfonamide compounds. This is particularly important if (1) the close contacts are children and (2) exposure occurs during an epidemic period. In the case of hypersensitivity to these compounds, penicillin provides an adequate substitute. Presumably the administration of a longer course of chemoprophylaxis to the members of a closed community would result in an appreciable period of freedom from these infections. Such a program should not be initiated without due consideration for the potential complications arising from the emergence of drug-resistant strains, not only of meningococci but of other bacterial pathogens as well in

the disease Sulfisoxazole (Gantrisin) has been the preferred drug because of its relatively low toxicity The equally effective sulfadiazine entails the risk of crystalluria particularly when administered parenterally although this hazard may be markedly reduced by alkalinization of the urine and maintenance of an adequate renal output The average uncomplicated case responds promptly to the administration of either of these sulfonamides when treatment is initiated early in the course of the disease If the patient is conscious oral administration of the drug will usually suffice although frequently a priming dose of parenterally administered drug is given at the onset of treatment in order to build up adequate levels in the blood as soon as possible In the unconscious or critically ill patient the drug must be administered parenterally Specific therapy must be maintained for several days after the patient s clinical course has returned to normal

Until recently primary sulfonamide resistant strains of meningococci were unknown and the emergence of drug resistant strains during therapy was not a problem In 1963 relatively high meningococcal carrier rates due to sulfonamide resistant strains of Group B were detected in 3 military installations in the United States (Millar 1963) This has led to a careful re-examination of the whole problem including the testing of many strains of the organism for sulfonamide sensitivity With one exception all strains of Group C have shown exquisite sensitivity to these drugs in the absence of recent outbreaks due to Group A organisms no new strains of this type have been available for testing Many but not all Group B strains have shown a slight but definite degree of resistance in the 3 instances described above resistance to sulfonamides was complete Further studies are required in order to determine if Group B meningococci are distinguished by their latent ability to develop resistance to the sulfonamide series of drugs The practical implication of these recent findings is that the critically ill patient or the one who fails to respond promptly and dramatically to sulfonamide therapy should be treated with a combination of agents Since excellent therapeutic results have been obtained with penicillin this is usually the drug of choice for combination with sulfisoxazole or sulfadiazine The broad spectrum antibiotics (notably chloramphenicol) are also effective Resistance to these agents or to penicillin has not been reported as yet.

The occurrence of acute meningococcemia accompanied by vascular collapse (the Waterhouse Friderichsen syndrome) calls for heroic measures including chemotherapy with both sulfisoxazole and penicillin and intravenous fluids (physiologic saline with 10% glucose) to combat shock Norepinephrine and cortisone (or hydrocortisone) have been given traditionally to relieve presumed adrenal insufficiency but the advisability of this procedure has been questioned recently (Margaretten and McAdams 1958 May 1960) Acute congestive failure due primarily to acute interstitial myocarditis is an important complication and the case fatality rate is high even in the presence of vigorous and sustained treatment

EPIDEMIOLOGY

Man represents the only recognized reservoir of the meningococcus The portal of entry and exit is the upper respiratory tract and the means of spread is essentially person to person via air borne droplets or by inanimate objects which are contaminated by the nasopharyngeal secretions of individuals carrying the organisms The extreme sensitivity of the organism to adverse physical conditions such as heat and low humidity means that intimate contact between two individuals is necessary for its spread

The clinical disease occurs both sporadically and in epidemics (Hirsch 1886) The latter show some evidence of cyclical occurrences (Gover and Jackson 1946 Hedrich 1952) with peaks of high prevalence occurring at 8 to 12 year intervals The incidence is usually highest in the late winter and early spring months summer and autumn show a significantly lower incidence of cases Young children are particularly at risk with some evidence suggesting a higher incidence in males than in females The case fatality rates are highest among the young and the aged

The identification of the causative organism the discovery of the multiplicity of antigenic types and the development of effective

The Gonococcus

INTRODUCTION

The gonococcus (*Neisseria gonorrhoeae*) is a gram negative diplococcus a species of the genus *Neisseria* to which belong also the meningococcus and several nonpathogenic inhabitants of mucous membrane including the anaerobic *Veillonella* (family Neisseriaceae)

The gonococcus is the cause of a number of contagious infections of human columnar and transitional epithelium Hence urethritis cervicitis salpingitis and other complications in adults vulvovaginitis in children and ophthalmia in the newborn and in adults are contagious inflammatory conditions all caused by the gonococcus The commonest is gonorrhea known in the vernacular as clap or strain

HISTORY

While most authors suggest that gonorrhea is a disease of great antiquity there is no conclusive proof to support this contention Ancient Egyptian prescriptions early Chinese and Japanese writings Biblical and Vedic references are suggestive but all of them are so vague that it is impossible to determine whether the writers had in mind a specific contagious urethritis or not The clearest descriptions of the progress do not suggest any inflammatory component or contagious character of the urethritides described Galen A D 130 first employed the term gonorrhea which may be translated as flow of seed As Vertue (1953) suggests Galen s own definition and description of gonorrhea is equivalent to what today is termed spermatorrhoea Support of this contention may be found in the contemporary writings of independent physicians such as Aretaeus the Cappadocian and Celsus of the first century A D From Hippocrates to Galen and still later the medical profession showed no general recognition of venereal disease When a contagious urethritis began to appear a place for it consistent with Galen had to be found Quite logically the term gonorrhea was chosen to carry the burden Gulielmus de Saliceto a 13th century physician of Placenza presumably dealt with this disease and was aware of its venereal origin

the course of prolonged chemoprophylaxis (Cheever 1945) If sulfonamide resistant strains of meningococci appear in significant numbers (Feldman 1963) this form of chemoprophylaxis will be sharply limited in value

As in the case of other air borne infections characterized by a high carrier rate attempts to prevent the spread of the causative organism by isolation and environmental control measures have met with little success No vaccine is available

The Gonococcus

INTRODUCTION

The gonococcus (*Neisseria gonorrhoeae*) is a gram negative diplococcus a species of the genus *Neisseria* to which belong also the meningococcus and several nonpathogenic inhabitants of mucous membrane including the anaerobic *Veillonella* (family Neisseriaceae)

The gonococcus is the cause of a number of contagious infections of human columnar and transitional epithelium Hence urethritis cervicitis salpingitis and other complications in adults vulvovaginitis in children and ophthalmia in the newborn and in adults are contagious inflammatory conditions all caused by the gonococcus The commonest is gonorrhea known in the vernacular as clap or strain

HISTORY

While most authors suggest that gonorrhea is a disease of great antiquity there is no conclusive proof to support this contention Ancient Egyptian prescriptions early Chinese and Japanese writings Biblical and Vedic references are suggestive but all of them are so vague that it is impossible to determine whether the writers had in mind a specific contagious urethritis or not The clearest descriptions of the progress do not suggest any inflammatory component or contagious character of the urethritides described Galen A D 130 first employed the term gonorrhea which may be translated as flow of seed As Vertue (1953) suggests Galen s own definition and description of gonorrhea is equivalent to what today is termed spermatorrhoea Support of this contention may be found in the contemporary writings of independent physicians such as Aretaeus the Cappadocian and Celsus of the first century A D From Hippocrates to Galen and still later the medical profession showed no general recognition of venereal disease When a contagious urethritis began to appear a place for it consistent with Galen had to be found Quite logically the term gonorrhea was chosen to carry the burden Gulielmus de Saliceto a 13th century physician of Placenza presumably dealt with this disease and was aware of its venereal origin

* The opinions or assertions contained herein are those of the authors and are not to be construed as official or reflecting the views of the Department of Health Education and Welfare or the U S Public Health Service

He attributed the affliction to impurities retained under the male prepuce after exposure to an unclean female and was the first to suggest prophylaxis by washing In a manuscript of 1376 by John of Arderne (John Arden) who was surgeon to Richard II and Henry IV, is found one of the first recorded descriptions of contagious urethritis comparable with contemporary gonorrhea In the following 3 centuries it is obvious that the initiated were well aware that this entity was a venereal contagion However a division arose in medical thinking as to whether gonorrhea was a separate disease or a manifestation of syphilis The history of gonorrhea began merging with syphilis on the appearance of the latter as a recognized entity in Western Europe at the close of the 15th century As early as 1530 Paracelsus taught that gonorrhea was an initial symptom of syphilis Indeed in those times the observed relationship was probably correct more often than not The concept that gonorrhea was a manifestation of syphilis reached its pinnacle of acceptance after the classic error of John Hunter who in 1767 misinterpreted the syphilis infection which resulted from self inoculation with pus from the urethra of a patient supposedly infected with gonorrhea Hunter s work so dominated medical thought that in spite of the excellent work of Hill in 1790 and Benjamin Bell in 1792 clearly differentiating gonorrhea from syphilis it remained for Phillippe Ricord in work extending from 1831 to 1860 to delineate the 2 diseases clearly and finally Noeggerath in 1872 published one of the first works discussing the prevalence of gonorrhea especially in women its resistance to therapy its highly infectious nature the insidious tendency to remain latent for prolonged periods and the serious nature of complications and sequelae In 1879 Neisser identified the causative organism of this disease which he called the gonococcus Subsequent to its discovery the gonococcus was first cultivated by Leistikow and Loeffler in 1882 but was more satisfactorily grown and studied by Bumm in 1885 The identification of the organism was simplified generally but not specifically by the introduction of the gram stain by Hans Gram in 1884 Finger Ghon and Schlagenhaufer in 1894 published a description of the histopathology of the disease based on the study of postmortem material obtained from patients artificially infected in the terminal stage of other diseases Muller and Oppenheim in 1906 applied the principles of complement fixation successfully to the diagnosis of gonorrhea Diagnostic technics in general improved little beyond this point until the recent observation that the fluorescent antibody technic was adaptable to the identification of *N gonorrhoeae* Treatment was advanced from the era of sandalwood oil by the introduction of potassium permanganate solutions for urethral irrigations by Janet in 1892 For over 4 decades only minor modifications of this basic technic were introduced in the treatment of the disease With the advent of the sulfonamides specific therapy seemed to be at hand but within a few years the optimism concerning these drugs was blasted by the ability of the gonococcus to become resistant to these drugs However the very striking susceptibility of *N gonorrhoeae* to penicillin was demonstrated in 1943 Confidence in the penicillin treatment of gonorrhea led to complacency not only concerning the ease of treatment of this disease but also in relation to curability and the complications which were less and less frequently seen in hospitals and clinical practice With the advent of penicillin many assumed that gonorrhea would be brought under control readily That this has not occurred can be demonstrated by reference to our national morbidity statistics The fallacy of the supposition that any disease can be controlled by treatment alone without due consideration of other aspects of its epidemiology is beautifully borne out by our experience with gonorrhea to date Until recently, about all that had been gained in the control of this disease during the little more than 85 years since the discovery of the gonococcus were some minor improvements in diagnosis a highly effective therapeutic agent which may have been squandered by our ignorance and an almost total prevention of serious complications of the disease in males Gonorrhea remains the largest and most challenging venereal disease problem in the western world

MORPHOLOGY

The gonococcus appears in the exudate of *acute gonorrhea* as a diplococcus with contiguous sides flattened or slightly concave resembling a pair of kidney beans and measuring from 0 6 to 1 0 micron in diameter In these exudates many polymorphonuclear leukocytes contain no ingested organisms while others display from a few to large numbers The gonococcus does not possess spores true capsules or flagella It is stained readily by aniline dyes and is gram negative Ordinary optical methods do not reveal any intracellular differentiation

Cells growing in laboratory media differ somewhat in appearance from those seen in pathologic material Cultures consist predominantly of diplococci but may also contain single cocci and clumps Older cultures frequently exhibit irregular staining giant forms Cellular morphology is altered progressively by contact with penicillin both in vitro and in vivo Smears of exudate taken during the first 4 or 5 hours of penicillin therapy show gonococcal forms that progressively enlarge and decrease in stainability until none can be detected

CULTIVATION AND CHARACTERISTICS

Primary cultivation of the gonococcus on laboratory media is difficult not only because the organism is fastidious in its growth requirements but also because it is exceedingly susceptible to the toxic effect of a variety of substances commonly present in ordinary media The organism grows best under aerobic conditions at pH 7 2 to 7 6 at a temperature of 35 to 36 C Some strains do not grow satisfactorily at 37 5 C and in general growth stops below 30 C or above 38 5 C Most strains require an atmosphere containing from 2 to 10 per cent CO to initiate development Although gonococci grow well on the moist surface of solid media containing 1 0 to 1 5 per cent agar excessive moisture as produced by syneresis of the agar is undesirable especially for primary isolation because it favors other bacteria especially spreaders which readily overgrow the more slowly growing gonococcus Satisfactory growth is obtained on agar media consisting of meat infusion peptones glucose buffered with phosphate and enriched with plasma and hemoglobin or whole blood Increased yields can result from the addition to the media of yeast or liver concentrate which supply glutamine and cocarboxylase shown by Lankford *et al* (1943 1946) to be essential for 10 to 15 per cent of gonococcus strains Kellogg *et al* (1963) have shown that hemoglobin solution or blood may be replaced by adding ferric nitrate to Lankford s supplement of glutathione cocarboxylase and glucose As mentioned earlier many components of media exert an inhibiting effect on the growth of gonococci Thus certain amino acids occur in peptones in concentration sufficient to be somewhat toxic but this effect can be reduced markedly or abolished by heating the medium after addition of blood (chocolate agar) Ley and Mueller (1946) have shown that agar containing excessive amounts of fatty acids also can exert an inhibiting effect on the growth of certain strains of gonococci and that the effect can be counteracted by charcoal or starch Advantage has been taken of all these facts in certain commercial media which are convenient for the isolation of gonococci from pathologic material The bacterial flora of urethral and cervical secretions contain organisms that grow very much more rapidly on artificial media than does the gonococcus Such overgrowth prevents the detection of gonococcus colonies Attempts to prepare a selective medium by the use of Nile Blue A or crystal violet were not very successful because these dyes were toxic to some gonococcal strains Recently an effective selective medium for the cultivation of *N gonorrhoeae* or *N meningitidis* has been developed by Thayer and Martin (1963) It has selective properties that permit cultivation of pathogenic *Neisseria* while greatly inhibiting or completely suppressing saprophytic species such as *N sicca N catarrhalis N flava* and others Overgrowth of gonococcal colonies by bacterial contaminants encountered in cervical vaginal and even rectal specimens is almost totally prevented and the diagnostically confusing *Mima polymorpha* var *oxi*

dans a microorganism sometimes confused with gonococci fails to grow Thus, false positive cultural diagnosis of gonorrhea due to oxidase positive *Mima* and saprophytic *Neisseria* is almost totally prevented Pre sumptive cultural testing (oxidase positive colonies of gram negative diplococci uncon firmed by sugar fermentation reaction) there fore becomes a more acceptable diagnostic procedure when definitive measures cannot be taken The Thayer Martin (TM) selec tive medium is of particular value for diag nosing the meningococcal carrier state Bac teria of the pharyngeal region including saprophytic *N catarrhalis N sicca* and others are almost totally inhibited allowing meningococci to grow and be picked from primary isolation plates for typing with group sera without the necessity of purification pro cedures The selective properties of the me dium are due to the action of polymyxin B (25 units/ml) against the gram negative bacterial flora and to the inhibition of the gram positive bacterial flora by ristocetin (10 mcg /ml) In the concentrations used gonococcal growth is slightly inhibited during the first 24 hours of incubation but not after 48 hours After 48 hours incubation the primary gonococcus colony appears trans lucent raised finely granular and slightly convex with lobate margins It is usually mucoid and varies in size from punctiform to 5 mm in diameter depending on the me dium and the crowding of the plate Although ordinary agar cultures die within 3 to 4 days unless transferred agar-slant cultures remain viable at 35° C for a considerable period of time if covered with sterile paraffin oil Cul- tures may also be kept for years if quick frozen and stored at −70° C

Glucose is the only sugar fermented by the gonococcus with the production of acid but no gas Other members of the genus *Neisseria* are encountered occasionally in specimens from the genital tract Fermentation reactions differentiate these species from the gonococ cus Some gonococcal strains fail to grow on media lacking adequate nutrients and a few isolates fail to ferment glucose initially (White *et al* 1964) Thus some so-called infections thought to be due to *N catarrhalis* may have been caused by non glucose fermenting gono- cocci Differentiation of such strains should include immunofluorescent studies (Gono coccus 1962)

The fact that the gonococcus produces an oxidase has been utilized for the recogni tion of gonococcal colonies on agar medium When 1 per cent aqueous solution of di methyl p phenylenediamine monohydrochlo ride is added to an agar growth the colonies turn pink then purple The reagent kills the organisms within a few minutes but does not modify their morphology or staining by Gram s or the fluorescent antibody method The oxidase reaction is often negative in media containing 1 per cent glucose due to inhibition of the enzyme by acid neutraliza tion with sodium bicarbonate results in a positive oxidase test (Bucca Thayer and Schubert, 1947) All members of the genus *Neisseria* give positive reactions, so do *Mima polymorpha* var *oxidans* some *Pseudo monas* and *Aeromonas* Variable results are given by *Bordetella Haemophilus* and some *Pasteurella* and yeasts (Steel 1961) These microorganisms may confuse the laboratory identification if adequate measures are not taken Nevertheless a positive oxidase re action coupled with typical colonial char acteristics and the presence of diplococci resembling the gonococcus constitutes pre sumptive cultural evidence which should be confirmed by sugar fermentation and/or fluorescent antibody procedures

As mentioned under ordinary conditions the gonococcus dies rapidly in agar cultures It is killed quickly by drying sunlight and ultraviolet light Moist heat at 55° C kills it in a few minutes Phenol bichloride of mercury and silver compounds are very effec tive disinfectants The gonococcus is more soluble than the meningococcus in dilute NaOH (within 1 minute) whereas other *Neisseria* are less soluble in this reagent Al though the gonococcus is susceptible to sul fonamides the range may vary from com plete resistance of certain strains which can synthesize para aminobenzoic acid to sus ceptibility to drug concentration readily ob tained in the blood Gonococcal strains for merly highly resistant to sulfonamide have again become sensitive during the era of penicillin therapy (Love and Finland, 1955

Thayer Field and Garson 1959) Resistance to sulfonamides and streptomycin is rapidly acquired in vitro

For almost a decade it appeared that the gonococcus would not become resistant to penicillin as it had to sulfonamides From 1945 to 1954 susceptibility studies in this country and abroad showed that of 771 cultures all but 5 strains were sensitive to 0 05 u /ml or less (Guthe 1961) In trying to explain the high failure rate of females treated with 600 000 units of procaine penicillin Thayer *et al* (1957a) found that 22 per cent of the patients cultures required 0 1 to 0 2 u /ml to inhibit in vitro growth Surveillance studies of treatment failure cases since that time have shown that the range of penicillin resistance is slowly expanding To day some isolates require over 1 0 u /ml for in vitro inhibition (Thayer 1963) Of the semisynthetic penicillins tested only ampicillin is as potent as benzyl penicillin G for sensitive and relatively resistant gonococci (Thayer and Axnick 1963b) In tissue culture intracellular gonococci may be protected against many times the minimal inhibitory concentration of penicillin chloramphenicol erythromycin novobiocin and the tetracyclines (Thayer *et al* 1957b c)

The gonococcus causes infection only in man numerous attempts to reproduce the disease in animals have failed However under certain conditions growth of minimal numbers of gonococci has occurred in embryonated eggs in the anterior chamber of the eye of the rabbit and in the mouse by intraperitoneal injection of gonococci suspended in mucin (Hill 1944) Kellogg and co workers (1963) have found that gonococci can be maintained virulent in culture Four morphologically distinct colonial types have been observed Type 1 is of most interest since it is found predominantly in the purulent exudate from acute gonorrhea of the male Other colonial types appear rapidly on subculturing the primary isolate probably due to genetic instability of the type 1 cells in vitro After 69 passages on suitable culture media type 4 cells typical of so-called laboratory strains were no longer virulent for male volunteers whereas type 1 cells readily produced gonococcal urethritis In the past studies in serodiagnosis and immunity have been performed with avirulent cultures

The toxicity of the gonococcus appears to be due entirely to a lipopolysaccharide endotoxin (Tauber and Garson 1959) The injection of heat killed gonococci results in toxemia and death similar to that produced by living cocci So far other chemical components separated from the gonococcus have not proved to be useful in the development of diagnostic tests Failure to detect significant levels of antibodies consistently by agglutination precipitation bactericidal complement fixation and allergy tests has been related to the fact that the infection stimulates little antibody formation because of its local character Genetic instability of the virulent culture also may have resulted in the preparation of nonspecific antigens (Reising and Kellogg 1963) However in controlled experiments volunteers displaying a positive gonococcus complement fixation test prior to inoculation did not develop disease with the same frequency as those recorded as having a negative test (Mahoney 1946)

CLINICAL COURSE

The usual incubation period of the natural infection is from 2 to 8 days and varies from 1 to 31 days with a mean of from 3 to 5 days in the experimental disease (Mahoney *et al* 1946) These experimental observations closely parallel clinical observations (Garson 1953 Haro and Patiala 1957)

The typical onset is sudden Usual symptoms consist of frequent urgent and painful urination and a profuse mucopurulent discharge The gonococcus is unable to penetrate stratified squamous epithelium however in the male the urethra with its stratified columnar epithelium is favorable for its penetration (Harkness 1948) Penetration takes place through the intercellular spaces the organism being observed to reach the subepithelial connective tissue on the 3rd or the 4th day Polymorphonuclear leukocytes lymphocytes plasma and mast cells soon appear beneath the columnar epithelium being particularly numerous in the region of Littre s glands and ducts and the lacunae of Mor

gagni Large numbers of leukocytes carrying gonococci find their way from the acutely inflamed area into the lumen of the urethra and form with serum the profuse yellow discharge characteristic of the disease The ducts of Littre s glands may become obstructed by leukocytes and desquamated epithelial cells resulting in the formation of retention cysts *or abscesses* Spread of the disease takes place by continuity from the subepithelial connective tissue and also directly into lymphatic vessels resulting in prostatitis and epididymitis Extension of pathology to subepithelial tissues and subsequent healing allows for con*tracture* which in annular structures may cause narrowing and stricture During heal*ing* stratified squamous epithelium appears over the granulating surface of denuded areas and may compress and destroy any underlying columnar epithelium

In the female the cervical glands Skene s glands and Bartholin s glands are usual sites of primary infection The rectum is frequently the site of secondary infection and occasionally the primary site Histologic pathology is similar to that described for the male urethra Involvement of cervical glands as for Littre s glands usually is confined to the ducts giving rise to a mucopurulent discharge of a degree ranging from mild to very severe

Progression to the fallopian tubes results in salpingitis usually bilateral There is a tendency for the tubes to close and form pyosalpinx and pelvic inflammatory disease Residual pathology in the tubal structures may require surgical correction after the inflammatory process has been brought under control In the glands of Bartholin unilateral inflammation is confined to the ducts and the periglandular tissue

The incidence of proctitis determined with the TM selective medium is found in 40 per cent of urogenital female gonorrhea An additional 5 per cent occurs at the rectal site only Among patients with proctitis gonococci are also found at the perianal site in 50 per cent of the cases (Schroeter and Yobs 1964)

N gonorrhoeae can be responsible for ophthalmia neonatorum an inflammation of the eye of the newborn resulting primarily from infection during passage through the birth canal The condition, which appears several days after birth is always serious is frequently destructive *to the ocular struc*tures and before the use of silver nitrate prophylaxis was credited *with being respon*sible for 12 per cent of all blindness Today the recorded incid*ence is less than 0 3* per cent where standard technics of prophylaxis are used That silver nitrate prophylaxis does not entirely prevent gonococcal ophthalmia was found by Pearson (1957) *who observed* 40 cases in 67 200 live births during a period of 10 years The ease with which gonococcal ophthalmia responds to antibiotic treatment has led to a relaxation of prophylactic measures in areas where postnatal supervision is satisfactory The risk of chemical conjunctivitis from silver nitrate may be avoided by antibiotic prophylaxis (penicillin erythromycin oxytetracycline bacitracin ointment and sulfathiozole) However such measures have not proved to be entirely satisfactory and in view of the increased incidence of gonorrhea there has been a return to silver nitrate prophylaxis

Gonococcal vulvovaginitis is an inflammation of the urogenital tract of prepubescent females and must be differentiated by bacteriologic means from that due to a variety of other infectious agents The disease is transmitted by intimate direct contact with infected adults and infrequently by contact with contaminated moist articles Cohn *et al* (1940) believe that epidemics rarely occur

DIAGNOSIS

Gram negative intracellular diplococci in the stained exudate from a suspected gonococcic infection strongly suggests gonorrhea The intracellular position of the gonococcus is a common finding in acute gonorrhea but in very early or chronic infection the organisms may be found only extracellularly frequently as a single coccus In men a diagnosis based on the characteristic clinical symptoms usually can be confirmed by the finding of intracellular gram negative diplococci in pus cells in the urethral discharge Preferably such presumptive evidence of *N gonorrhoeae* should be confirmed by culture methods including identification by sugar fermentation

An outstanding diagnostic advance is the

immunofluorescent method for the detection and the identification of gonococci in exudate The procedure developed by Deacon *et al* (1959 1961) employs an immediate direct fluorescent antibody (FA) method and a delayed FA technic In the former complete identification as *N gonorrhoeae* may be obtained within 1 hour The delayed FA method which is more effective than the immediate direct method for diagnosing the asymptomatic female (Brown *et al* 1962) requires a 16 to 20 hour preliminary cultivation of exudate to accumulate gonococci in sufficient numbers for detection by fluorescent microscopy The chief advantages of the delayed FA procedure over the conventional clinical culture method are the time required to make a definitive diagnosis—16 to 20 hours against 2 to 10 days respectively—and the greater sensitivity of the technic in most laboratories In a field evaluation of the FA method by public health and university laboratories (Price 1964) over 85 000 specimens from urethral cervical and vaginal sites of 9 483 females were examined Using immediate direct and delayed FA methods and the classic culture method gonococci were detected by culture in 22 per cent by delayed FA in 37 per cent and by direct FA in 15 per cent When female contacts of persons having gonorrhea were studied the culture was positive in 59 per cent immediate direct FA 43 per cent and delayed FA in 79 per cent of 1 782 patients Some workers (Moore *et al* 1963) feel that the FA procedure occasionally gives a false positive result Peacock (1961) has greatly reduced the likelihood of false positive staining of staphylococci by applying the one step inhibition technic for blocking antistaphylococcal antibodies present in normal rabbit serum Peacock (1964) has also controlled background and polymorphonuclear cell staining with Flazo Orange With the use of this dye or Evans Blue (White and Kellogg 1964) counterstained direct FA smears prepared on a small defined area of the slide with a bacteriologic loopful of specimen increases the sensitivity of the procedure

Trauma or the introduction of mechanical and chemical irritants into the urethra may give rise to an inflammatory process which has some of the characteristics of gonorrhea but can be differentiated by negative bacteriologic findings Similarly a condition designated as nongonococcal urethritis or nonspecific urethritis is encountered Instead of a burning sensation during urination as with gonorrhea an itching sensation of the urethral canal and pain referred to the glands occurs independent of urination The discharge is thinner gray to white in color and usually less profuse than gonorrhea The presence of *N gonorrhoeae* or *Trichomonas vaginalis* must be ruled out

Mistakes in the microscopic diagnosis of gonorrhea may be made when gram positive cocci are overly destained or gram negative diplo bacilli are wrongly identified as gonococci Also the morphology of the *Mima Herella* group of organisms is quite similar to gonococci especially in exudates and from growth on enriched media Differentiation is easily made on meat extract agar unenriched broth or eosin methylene blue agar media on which *Mima* and *Herella* assume their rodlike form and on which the gonococcus does not grow Where gonococcal FA procedures are available differentiation is rapidly made Other than a single outbreak of a gonorrhealike syndrome caused by *Mimeae* in Italy (Svihus *et al* 1961) no microbial agent other than *N gonorrhoeae* has the capacity to produce acute infectious urethritis consistently in the human

Gonorrhea of the female may be signless and symptomless Thus laboratory diagnosis is more difficult than in men Stained smears are of value in early infections when typical intracellular organisms may be found in material from the urethra or the cervix As the age of the infection advances the value of the smear decreases while that of the culture and the delayed FA methods increases Fortunately the use of immunofluorescent methods and selective culture media has improved diagnosis but these procedures still fail to diagnose 20 to 40 per cent of female contacts of persons having gonorrhea (Price 1964) It should be pointed out in this connection that in chronic untreated gonorrhea culture findings may reverse spontaneously from positive to negative without any accompanying change in the clinical status of the infection Furthermore sporadic positive cultures may appear after a relatively

long series of negative cultures (Mahoney *et al* 1942)

Serodiagnosis using present methods of *complement fixation (gonoreaction) are not* sufficiently reliable to identify active disease in males or asymptomatic females (Van Slyke *et al* 1942 Nøgaard 1956 Brown, 1963) *Such a tool is urgently needed for the epi*demiologic control of gonorrhea

Schubert *et al* (1947) showed that gonorrheal exudate inoculated directly on the agar surface in the clinic and incubated shortly thereafter gave the greatest yield of positive cultures When this is not possible the swab containing the exudate should be placed in a small amount of broth and taken to the laboratory Difficulties inherent in the isolation of the gonococcus are increased when the clinician fails to exercise care in securing suitable exudates for cultivation The demonstration of gonococci in cervical exudate is said to be most favorable during the post menstrual phase However other workers prefer the premenstrual phase and some even choose the menstrual period Putkonen (1950) studied this problem in 343 patients hospitalized for gonorrheal cervicitis in whom *menstruation was known in relation to 1 119* examinations He found no significant variation of positive cultures in relation to the day of the menstrual cycle

The transportation of suspected secretions from the patient to a distant laboratory for cultural diagnosis has not been very successful An ideal transport medium must preserve *the viability of the gonococcus and at the* same time prevent overgrowth of contaminating bacteria Stuart (1954) uses a buffered nonnutrient agar medium to which thioglycollate is added In theory viable gonococci are preserved and contaminants fail to grow for lack of nutrients Specimens of blood synovial fluid and spinal fluid are cultivated best in shallow layers of ascitic fluid broth in an atmosphere containing from 2 to 10 per cent CO after incubation for 2 to 7 days the organisms grow as a mucoid sediment on the bottom of the flask Urine preferably the first morning specimen should be centrifuged and the sediment inoculated on agar medium Prostatic fluid may be inoculated directly on agar or centrifuged in a small amount of urine the sediment being inoculated on agar For more detailed information concerning the collection of specimens and the culture method see *Gonococcus—Procedures for Isolation and Identification* (1962)

In general, because of the characteristic clinical signs and symptoms, presumptive cultural evidence of gonococcal infection (unconfirmed by sugar fermentation) is more acceptable for diagnosis of gonorrhea in the male than in the female *In the female in* whom clinical evidence is of little value a negative smear report coupled with presumptive cultural evidence has led to as high as *16* per cent false positive diagnoses (Thayer *1958*) *Such* results are unlikely to occur, as already mentioned, if the TM selective medium is used (see Cultivation)

TREATMENT

The advent of chemotherapy in 1935 rapidly reduced such practices as the local application of antiseptic and astringent solutions by means of injection irrigations and instillations and of attempts to alkalinize the urine All of these methods are of question*able efficacy and may have added to the com*plications of gonorrhea Sera vaccines and culture filtrates have also proved to be of very limited if any value Artificial hyperpyrexia *based on the marked heat lability of the* gonococcus is no longer practiced When the sulfonamide compounds and subsequently penicillin became available the therapy of *gonorrhea passed from the province of urol*ogy and to a lesser extent, gynecology to that of chemotherapy largely in the hands of the general practitioner

Although the past recommended practice of employing 600 000 units of a repository penicillin in a single intramuscular injection for the routine treatment of uncomplicated gonorrhea has given excellent results in males Preston and Dunsworth (1957), Hookings and Graves (1956 57) and others have demonstrated at least a 13 to 15 per cent failure rate in females in clinic populations In general it has been alleged that as much as 2 to 5 per cent of males and 10 to 20 per cent of females failed to be cured by the single intramuscular injection of 600 000 units of *repository penicillin. The reason for such*

treatment failures in the face of the once rather remarkable susceptibility of the gonococcus to penicillin has been explored by Thayer *et al* (1957a 1962) Other than failures related to (1) misdiagnosis including nongonococcal urethritis other causes include (2) reinfection on return to the original infecting sexual environment (3) the use of drugs in inadequate doses or of drugs rendered useless by prior mishandling or deterioration (4) factors such as the effect of penicillinase producing staphylococci on male urethritis (Kjellander and Finland 1963) and the persistence of female proctitis (Bang 1954) and (5) the relative resistance of certain strains of *N gonorrhoeae* to penicillin (Thayer *et al* 1961)

The increasing incidence of treatment failure has led to modification of the recommended drug therapy regimen In place of the one shot treatment the following procedures are now recommended

Uncomplicated gonorrhea in men aqueous procaine penicillin G procaine penicillin G in oil with 2 per cent aluminum monostearate (PAM) 2 400 000 units in 1 intramuscular injection

Uncomplicated gonorrhea in women aqueous procaine penicillin G or PAM 4 800 000 units intramuscularly in 2 injection sites at one visit In view of the increased resistance of gonococcal strains to penicillin long acting penicillins which produce low blood concentrations such as benzathine penicillin G are no longer indicated in the management of most gonorrheal infections

Gonorrhea with severe complications generally should be treated with aqueous crystalline penicillin G 4 800 000 to 10 000 000 units per day intramuscularly given at 2 to 4 hour intervals or equivalent amounts of a penicillin producing a high blood level until signs and symptoms have subsided and cultures if obtainable are negative The management of most complications is more appropriately handled in the hospital where resources of consultation and special laboratory procedures are more readily and rapidly available

Retreatment usually is indicated if on the exclusion of the likelihood of reinfection the discharge persists for 3 days or more after initial treatment and smear culture or FA diagnosis is still positive In general the retreatment dose consists of a doubling of the original schedule at a single session or equally divided injections of the increased dose over a period of 3 to 5 days until the total dosage is achieved and signs and symptoms have subsided

The need for local therapy prostatic massage or artificial hyperpyrexia is seldom if ever encountered So-called prophylactic or epidemiologic treatment should be given to all sexual contacts of a positively diagnosed case of gonorrhea The recommended treatment for such contacts is as given for uncomplicated gonorrhea above

While there is no evidence of absolute or rapidly increasing resistance of *N gonorrhoeae* to penicillin studies of gonococcal strains in this country since 1955 show a relentless expansion of the susceptibility range varying today from 0 005 to 1 20 units per ml (Thayer and Moore 1964) The relatively resistant strains of the organism in cases of presumed treatment failure on routine dosage schedules usually will respond satisfactorily to increased dosage

Approximately 15 commercially available antibiotics are as effective as penicillin G at the 1 2 mega unit dose Indeed a single (1 5 Gm) oral dose of phosphate potentiated tetracycline was observed to have a failure rate in acute gonorrhea of males of 5 7 per cent as compared to 8 4 per cent with 1 2 mega units of aqueous procaine penicillin G given by intramuscular injection (Tiedemann 1962) Among the newer injectable antibiotics actinospectacin in a single intramuscular dose (1 5 to 2 0 Gm) has been observed to fail in between 4 3 and 7 9 per cent of cases however resistance to this drug has been reported (Laird 1962 Willcox 1962) Few of the newer antibiotics are serious competitors of penicillin in the treatment of gonorrhea when one considers such factors as mode of administration dose toxicity side-effects and cost They should be considered only in the treatment of patients known to be sensitive to penicillin

Brown (1961b) in a re-evaluation of reactions to penicillin studied 35 494 patients treated in venereal disease clinics and found that an average of 9 71 patients per 1 000

long series of negative cultures (Mahoney *et al* 1942)

Serodiagnosis using present methods of complement fixation (gonoreaction) are not sufficiently reliable to identify active disease in males or asymptomatic females (Van Slyke *et al* 1942 Nøgaard 1956 Brown 1963) Such a tool is urgently needed for the epidemiologic control of gonorrhea

Schubert *et al* (1947) showed that gonorrheal exudate inoculated directly on the agar surface in the clinic and incubated shortly thereafter gave the greatest yield of positive cultures When this is not possible the swab containing the exudate should be placed in a small amount of broth and taken to the laboratory Difficulties inherent in the isolation of the gonococcus are increased when the clinician fails to exercise care in securing suitable exudates for cultivation The demonstration of gonococci in cervical exudate is said to be most favorable during the post menstrual phase However other workers prefer the premenstrual phase, and some even choose the menstrual period Putkonen (1950) studied this problem in 343 patients hospitalized for gonorrheal cervicitis in whom menstruation was known in relation to 1,119 examinations He found no significant variation of positive cultures in relation to the day of the menstrual cycle

The transportation of suspected secretions from the patient to a distant laboratory for cultural diagnosis has not been very successful An ideal transport medium must preserve the viability of the gonococcus and at the same time prevent overgrowth of contaminating bacteria Stuart (1954) uses a buffered nonnutrient agar medium to which thioglycollate is added In theory viable gonococci are preserved and contaminants fail to grow for lack of nutrients Specimens of blood synovial fluid and spinal fluid are cultivated best in shallow layers of ascitic fluid broth in an atmosphere containing from 2 to 10 per cent CO_2 after incubation for 2 to 7 days the organisms grow as a mucoid sediment on the bottom of the flask Urine preferably the first morning specimen should be centrifuged and the sediment inoculated on agar medium Prostatic fluid may be inoculated directly on agar or centrifuged in a small amount of urine the sediment being inoculated on agar For more detailed information concerning the collection of specimens and the culture method see Gonococcus—Procedures for Isolation and Identification (1962)

In general because of the characteristic clinical signs and symptoms presumptive cultural evidence of gonococcal infection (unconfirmed by sugar fermentation) is more acceptable for diagnosis of gonorrhea in the male than in the female In the female in whom clinical evidence is of little value a negative smear report coupled with presumptive cultural evidence has led to as high as 16 per cent false positive diagnoses (Thayer 1958) Such results are unlikely to occur as already mentioned if the TM selective medium is used (see Cultivation)

TREATMENT

The advent of chemotherapy in 1935 rapidly reduced such practices as the local application of antiseptic and astringent solutions by means of injection irrigations and instillations and of attempts to alkalinize the urine All of these methods are of questionable efficacy and may have added to the complications of gonorrhea Sera, vaccines and culture filtrates have also proved to be of very limited if any value Artificial hyperpyrexia based on the marked heat lability of the gonococcus is no longer practiced When the sulfonamide compounds and subsequently penicillin became available the therapy of gonorrhea passed from the province of urology and to a lesser extent gynecology to that of chemotherapy largely in the hands of the general practitioner

Although the past recommended practice of employing 600 000 units of a repository penicillin in a single intramuscular injection for the routine treatment of uncomplicated gonorrhea has given excellent results in males Preston and Dunsworth (1957) Hookings and Graves (1956 57) and others have demonstrated at least a 13 to 15 per cent failure rate in females in clinic populations In general it has been alleged that as much as 2 to 5 per cent of males and 10 to 20 per cent of females failed to be cured by the single intramuscular injection of 600 000 units of repository penicillin The reason for such

available on incidence and prevalence nonetheless there remain tantalizing unknowns and inconsistencies The long known relationship of the social and behavioral patterns of promiscuity sexual freedom and irresponsibility to the continued presence of this disease is well established Gonococcal infection is maintained by the continued presence of the venereal form which in turn is maintained by indiscriminate sexual behavior

The distribution and the occurrence of gonorrhea is world wide Available data would suggest that it is more common among persons of lower socio-economic status but it is not restricted to this group It affects both sexes and practically all ages but particularly the age groups of greatest sexual activity In the United States the highest incidence is found in the age group 20 to 24 years Many states indicate that 25 per cent of the gonorrhea reported occurs among teenagers Studies of the U S Public Health Service have indicated that 50 per cent and more of the individuals involved in epidemics of gonorrhea are in the teenage group It has been estimated that in the United States a teenager is infected with venereal disease every 11 minutes The source of infection is exudate from mucous membranes of infected persons and man is the only known reservoir Asymptomatic carriers have been reported recently from England and the United States Although the number of such individuals is relatively small they are nevertheless important for the control of the disease The mode of transmission is almost wholly by sexual intercourse with the exception of the ophthalmic infection acquired by the newborn during passage through an infected birth canal Intimate contact on the proper type of mucous membrane is absolutely essential for the transmission of this disease and the role of intermediary objects in transmission seems to be inconsequential As indicated elsewhere the incubation period has wide variation while the period of communicability may be from months to years unless interrupted by adequate therapy which ends communicability within hours or days Susceptibility is general and instances of racial immunity have not been recognized The popular belief that an infection contracted from a member of a certain race or in a certain geographic area is more severe or more resistant to treatment than others has no factual basis Spontaneous recovery of the anterior urethritis in men is usual eventually in the absence of excessive sexual activity or reinfection Ricord s statement over a century ago is still applicable to recovery in women We know when gonorrhea begins but God alone knows when it will end Acquired immunity has not been demonstrated and one attack does not protect against subsequent infection

Males vary greatly in their resistance to experimental infection Mahoney *et al* (1946) inoculated a large number of male volunteers by instillation of massive doses of cultures into the urethral canal In a total of 245 experimental exposures typical clinical disease with confirmatory laboratory findings was produced in only 83 or 33 8 per cent In the remainder a train of irritative symptoms of varying severity that persisted for periods ranging from several hours to 2 days was followed by a return to normal More recently Kellogg *et al* (1963) and Thayer (1964b) have been able to infect male volunteers in 95 per cent of the trials by using gonococcal cultures of type 1 clones The relatively low incidence of the infection among prostitutes may possibly be the expression of such natural resistance although it is known that the well initiated among this group practice a wide variety of empiric prophylactic technics in the process of scrubbing the decks aimed at professional self preservation

In culture studies carried out over several years Van Slyke *et al* (1942) found approximately 20 per cent of incarcerated prostitutes and other sex offenders to be infected A similar percentage has been found among female jail inmates studied by the delayed FA test (Harris *et al* 1962) National morbidity statistics in the past two decades indicate a decline and then a rise in reported cases of gonorrhea From 1947 to 1956 there was a 40 per cent decrease in reported cases and a 47 per cent decrease in the rate Any optimism concerning this favorable trend in morbidity should have been tempered by the fact that during this period simplified antibiotic treatment was developed and more and more cases were seen by private physicians who failed to report

showed penicillin sensitivity, ranging from mild signs to severe anaphylactic reactions The prospect of having to handle the sudden emergency of penicillin anaphylaxis makes it essential that no physician or clinic under take penicillin treatment without the proper equipment drugs and professional com petence

Cure in men implies complete freedom from clinical evidence of the disease how ever an asymptomatic persistent infection can develop (Pariser 1964) Examination for evidence of residual gonococcic infection may be done about 7 days after the comple tion of therapy The test of cure should con sist of culture and FA procedures The ma terial for culture should be obtained from the urethra with a platinum loop and from sedi mented urine Expression of the urethral glands by gentle massage of the canal and prostatic massage has been employed In strumentation as an aid in determining the presence of gonococci is not necessary and is not advised In general a test of cure is considered to be unnecessary in males in the absence of signs or symptoms of gonorrhea however evidence of the infection in sexual partners in the absence or signs and symp toms should be sought In this regard the male homosexual presents a special problem While the tendency of the infection to pro duce asymptomatic carrier states is greater than previously thought most patients har boring the gonococcus will display sooner or later clinical evidence of infection

In women repeated cultures and FA pro-cedures of carefully selected material from the cervix Skene s glands Bartholin s glands the vagina and the rectum offer the only available means for detecting residual infec tion At least one culture should be obtained from these sites from 7 to 10 days after treat ment If prolonged acting penicillin has been used penicillinase must be incorporated in the culture medium As a precautionary measure in both men and women unpro tected sexual exposure should be interdicted until the criteria of cure have been satisfied Relapse if it occurs will be seen most com monly in the first week after treatment Oc casionally it is found that what appears to be a relapse or treatment failure is a rein fection contracted from a regular sex partner who has not been given treatment or is un discovered for lack of proper epidemiologic studies

An exceptional circumstance is presented when gonorrhea and syphilis or other vene real diseases are contracted concurrently This is by no means a rare occurrence Some 3 per cent of the patients attending VD clinics have acquired syphilis and gonorrhea simultaneously In these instances the gono coccal infection because of its short incuba tion period becomes evident while the syphilitic infection is still in the preclinical or incubation stage Penicillin therapy di rected toward the cure of gonorrhea if in the amount and the type of preparation suggested previously will allow for the aborting of an oncoming syphilitic infection in practically all instances Garson (1963) has proposed a single injection treatment for all acute gonor rhea predicated on the penicillin curative dose for all forms of early syphilis In effect then the treatment of gonorrhea truly becomes a major element in the control of syphilis The occurrence of chills or fever (Herxheimer reaction) accompanying penicillin therapy of gonorrhea is strong presumptive evidence of the coexistence of syphilis as shown by by Fromer et al (1946) Hence all patients who are to receive penicillin treatment for gonorrhea should have a serologic test for syphilis prior to or at the time of treatment and monthly for 4 months after the comple tion of treatment The same precautions should be observed in patients receiving pro phylactic treatment and treatment with other antibiotics

EPIDEMIOLOGY

Reliable information on the incidence and the prevalence of the disease depends on faithful reporting of diagnosed cases As previously indicated it is extremely difficult to diagnose some cases of gonorrhea par ticularly in the female This fact plus the inadequacy of reporting cases makes it prac tically impossible to accumulate any reliable data on prevalence As a consequence figures concerning incidence represent only a por tion of the true picture Although knowledge of the natural history and the course of this disease is considerably better than information

argument but the further assumption that these factors alone would greatly modify the epidemiology of gonorrhea and bring about a marked decline in the prevalence of the disease is not valid The solution of one facet of the problem led to and was largely offset by the increased opportunity for reinfection Because of the short incubation period an increase in the number of reinfections in a given period of time will greatly swell the morbidity statistics and tend to maintain the disease in society Thus the hoped for decline in the prevalence and the incidence of gonorrhea following the introduction of effective antimicrobial agents has not occurred indeed reported cases of gonorrhea have shown a consistent significant upward trend since 1958

Becoming aware of the limitations of gonorrhea control programs the U S Public Health Service in 1952 with the cooperation of State Health Departments and selected large cities in the United States initiated the first major attempt to incorporate known epidemiologic information into a new methodology The technic was called speed zone epidemiology (peppy epi) It is an attempt to apply specialized technics in gonorrhea case finding interviewing and investigation of contacts as well as patient education which will exploit the characteristics of this disease Mahoney *et al* (1946) had demonstrated that the incubation period of experimentally acquired gonorrhea in males has a 31-day range but that 85 per cent of the infections produced clinical symptoms within 6 days Presumably then the bulk of case finding could be narrowed down in at least 85 per cent of all cases to the epidemiologic investigation of sex contacts of gonorrhea patients for the period beginning 6 to 7 days prior to the onset of clinical symptoms and ending at the time of appearance at the clinic If valid information were obtained at interview of the patient with gonorrhea the source case and the spread or contact cases would be identified and hopefully located and brought in for treatment thereby breaking the chain of infection surrounding the particular patient Since at that time penicillin in aluminum monostearate was the longest acting penicillin available and presumably protected the patient from reinfection for at least 72 hours and since reinfection from the same sources without such protection was known to be common and since developed interviewing technics had been proved to be highly effective in identifying contacts investigation of the patient s contacts had to be accomplished within the treated patient s penicillin protective period i e 72 hours Rapid investigation is therefore essential for breaking the chains of infection and protecting the patient from reinfection The most commonly employed technics to bring sex contacts to clinic observation within the 72 hour period were (1) a telegram to the contact requesting immediate appearance at the health department (2) an immediate telephone call to the contact (3) the immediate assignment of the contact not having an adequate address or telephone number or not responding to these technics to a venereal disease investigator and (4) having the informant bring in his contacts within 24 hours of the informant s treatment

Only male patients with diagnosed gonorrhea were interviewed for sex contacts Most well run large clinics had observed that the stimulus supplied to the patient by gonococcal urethritis was sufficient to attain excellent volunteer reporting by males As the females in most instances were completely unaware or belatedly aware of their gonococcal involvement female volunteering could not be depended on Hence adequate case finding among females depended on male cooperation in the identification of sex contacts Occasionally local circumstances will dictate the need for interviewing female cases for contacts The recent successful application of a modification of the syphilis control procedure termed cluster technic has been reported by Brown (1961a) The next essential is the immediate treatment of all sexual contacts brought to the observation of the clinic whether they are diagnosed on observation as gonorrhea or not

Utilizing this technic in a large mid Southern city over a 1 year period it was possible to obtain an index of 1 7 sex contacts per patient interviewed and to bring approximately 85 per cent of the sex contacts to clinic observation and treatment within 72 hours with 50 to 75 per cent of

them There was an almost inconsequential decrease in the rate and the number of cases reported during the 5 years from 1952 to 1956 Beginning in 1957 there has been a continual yearly increase in gonorrhea It has been estimated that the actual incidence of gonorrhea is between 5 and 10 times the number of cases reported (Curtis 1963)

PROPHYLAXIS

Mechanical prophylaxis by means of a condom offers the only type of protection on which any reasonable reliance can be placed In the male transmission of the disease is effected by the contamination of the very distal portion of the urethral mucosa On hypothetical grounds any chemical agent capable of destroying *N gonorrhoeae* while the organisms occupy a vulnerable position on the surface of the mucous membrane should serve as an effective prophylactic However there is no acceptable evidence that the commercial chemical prophylactic preparations or those used in military organizations have any appreciable degree of effectiveness In women mechanical cleansing with soap and water or with mild antiseptic solution offers a theoretical but unconfirmed mode of protection The prophylactic use of penicillin has been explored by the Armed Forces in high incidence areas The utilization of a single oral benzathine penicillin G tablet (250 000 units) is employed in the following ways either on embarking for short term leave or on return from leave 1 penicillin tablet is given to all personnel similarly a tablet may be given on reporting exposure The employment of such a technic on all personnel while indicated under certain circumstances, has been criticized from the standpoint of initiating penicillin hypersensitivity in a certain proportion of the personnel and because of the rather large cost of such a program per gonorrhea case prevented In a well-disciplined group it would appear that the best utilization of this technic would be based on personnel reporting exposure In any event this measure is considerably more effective in the prevention of gonorrhea than the chemical prophylaxis formerly utilized by the Armed Forces

All contacts of patients with gonorrhea should be identified located and treated as soon as possible Of course such contacts should be examined to determine their diagnostic status but regardless of whether the examination indicates the presence of gonorrhea or not all such contacts should be treated because of delays and difficulties in diagnosis particularly in females and the practical fact that sexual exposure usually continues despite advice to the contrary under such circumstances Every effort should be made to include all sexual contacts of the 6 to 10 days prior to the onset of the clinical infection as well as those contacts occurring from the time of onset until the patient is first seen

CONTROL MEASURES

The control of communicable diseases is based upon 4 major principles namely quarantine immunization eradication of the intermediate host, and specific treatment When we attempt to apply these principles to gonorrhea we become more fully aware of the difficulties in the control of this disease The success of the quarantine of cases and contacts depends in large measure on the capacity and the resources available to diagnose cases and find contacts The admitted deficiencies in ability to diagnose this disease particularly among females and the staggering job of attempting to find and process properly and handle perhaps 2 000 000 of our population make quarantine both impractical as well as politically unfeasible We have no means of artificial immunization for this disease and to worsen the situation no effective natural immunity is acquired by having the disease Man is the only known reservoir of gonorrhea and there is no intermediate host to eradicate A special treatment is available but specific therapy alone given to diagnosed cases without the aid of one or more of the other principles of control cannot control a social disease of this nature

It has been assumed that the general use of penicillin therapy would both reduce the period of infectiousness and decrease opportunities for transmission That these assumptions are correct there can be no

argument but the further assumption that these factors alone would greatly modify the epidemiology of gonorrhea and bring about a marked decline in the prevalence of the disease is not valid The solution of one facet of the problem led to and was largely offset by the increased opportunity for re infection Because of the short incubation period an increase in the number of rein fections in a given period of time will greatly swell the morbidity statistics and tend to maintain the disease in society Thus the hoped for decline in the prevalence and the incidence of gonorrhea following the intro duction of effective antimicrobial agents has not occurred indeed reported cases of gonorrhea have shown a consistent signifi cant upward trend since 1958

Becoming aware of the limitations of gonorrhea control programs the U S Pub lic Health Service in 1952 with the coopera tion of State Health Departments and selected large cities in the United States initiated the first major attempt to incor porate known epidemiologic information into a new methodology The technic was called speed zone epidemiology (peppy epi) It is an attempt to apply specialized technics in gonorrhea case finding interviewing and investigation of contacts as well as patient education which will exploit the characteris tics of this disease Mahoney *et al* (1946) had demonstrated that the incubation period of experimentally acquired gonorrhea in males has a 31-day range but that 85 per cent of the infections produced clinical symptoms within 6 days Presumably then the bulk of case finding could be narrowed down in at least 85 per cent of all cases to the epidemiologic investigation of sex con tacts of gonorrhea patients for the period beginning 6 to 7 days prior to the onset of clinical symptoms and ending at the time of appearance at the clinic If valid informa tion were obtained at interview of the pa tient with gonorrhea the source case and the spread or contact cases would be identi fied and hopefully located and brought in for treatment thereby breaking the chain of infection surrounding the particular patient Since at that time penicillin in aluminum monostearate was the longest acting penicil lin available and presumably protected the patient from reinfection for at least 72 hours and since reinfection from the same sources without such protection was known to be common and since developed interviewing technics had been proved to be highly effective in identifying contacts investiga tion of the patient s contacts had to be accomplished within the treated patient s penicillin protective period i e 72 hours Rapid investigation is therefore essential for breaking the chains of infection and protect ing the patient from reinfection The most commonly employed technics to bring sex contacts to clinic observation within the 72 hour period were (1) a telegram to the contact requesting immediate appearance at the health department (2) an immediate telephone call to the contact (3) the im mediate assignment of the contact not having an adequate address or telephone number or not responding to these technics to a ven ereal disease investigator and (4) having the informant bring in his contacts within 24 hours of the informant s treatment

Only male patients with diagnosed gonorrhea were interviewed for sex contacts Most well run large clinics had observed that the stimulus supplied to the patient by gonococcal urethritis was sufficient to attain excellent volunteer reporting by males As the females in most instances were com pletely unaware or belatedly aware of their gonococcal involvement female volunteering could not be depended on Hence adequate case finding among females depended on male cooperation in the identification of sex contacts Occasionally local circumstances will dictate the need for interviewing female cases for contacts The recent successful ap plication of a modification of the syphilis control procedure termed cluster technic has been reported by Brown (1961a) The next essential is the immediate treatment of all sexual contacts brought to the observa tion of the clinic whether they are diag nosed on observation as gonorrhea or not

Utilizing this technic in a large mid Southern city over a 1 year period it was possible to obtain an index of 1 7 sex con tacts per patient interviewed and to bring approximately 85 per cent of the sex con tacts to clinic observation and treatment within 72 hours with 50 to 75 per cent of

them There was an almost inconsequential decrease in the rate and the number of cases reported during the 5 years from 1952 to 1956 Beginning in 1957 there has been a continual yearly increase in gonorrhea It has been estimated that the actual incidence of gonorrhea is between 5 and 10 times the number of cases reported (Curtis 1963)

It has been assumed that the general use of penicillin therapy would both reduce the period of infectiousness and decrease opportunities for transmission That these assumptions are correct there can be no

Disease Program, U S Public Health Service is still timely

Venereal disease is unique among the communicable infections in that it is not wholly a clinical problem Its roots lie in the socially unacceptable environment in social maladjustment The venereal disease control program deals with the dilemma that is apparent that is the presence of a venereal disease Our services are specific we treat the infected individual and try to give him enough information so that he will not become reinfected or if he does that he will know what to do about it However we only skirt the edges when we look at the clinical aspects of the disease and do not deal with the deeper social causes or remote origin of the person s present difficulties

the contacts being treated within 24 hours it allowed for a significant reduction in morbidity over the previous year Although not universally successful these programs demonstrate the possibility of rapid investigation and stimulate new and better epidemiologic technics for more practical and economic control

Excellent results of the use of this technic in Canada have been reported by Anderson and Nelson (1954) and Nelson (1957) A most worthwhile and interesting by product of speed zone epidemiology programs has been the rather dramatic reduction in syphilis in the same population groups with no effort being expended other than the usual technics which were in vogue prior to the addition of the gonorrhea program Presumably the significant reduction in syphilis was due to the aborting of incubation or preclinical syphilis as a result of penicillin treatment on a fairly continuous basis

As indicated speed zone epidemiology as a technic for gonorrhea control is hardly a panacea This is understandable when one considers that such programs allow that at least 15 per cent of the contacts named within the jurisdiction of the health department are not located and brought to treatment Other limitations are the occasional failure at interview to obtain any contacts from the patient with gonorrhea contacts outside the jurisdiction of the health agency misinformation given by the informant to cover up his real contacts the undetermined number of unknown cases of gonorrhea in the population at any one time through the failure of the infected individual to seek ethical medical aid

The observations of Hookings (1956 57) on the utilization of combined penicillin aluminum monostearate and benzathine penicillin G in the gonorrhea speed zone project in Memphis Tenn represents perhaps the first breakthrough in increasing the effectiveness of such control programs since their initiation in 1952 On January 1 1956 the Memphis clinic began to treat female contacts and patients with 600 000 units of penicillin aluminum monostearate plus 1 200 000 units of benzathine penicillin G At the same time the records of all female contacts were tagged so that any repeat visit to the clinic would be readily recognized By the end of 60 days the repeat rate which had been 15 per cent in 1955 had dropped to 1 7 per cent A decline was seen in the weekly male attendance at the clinic when compared with the previous 2 year period On April 1 1956 males as well as females began to receive the combined treatment Since that time there has been an increasingly marked decline in male as well as female attendance at the clinic Careful scrutiny of all other factors which could account for such a decline were made and no factor other than the change in the treatment schedules utilized in the speed zone program could be detected Continuation of this approach for the remainder of 1956 allowed for a decrease in morbidity of approximately 1 100 cases over the previous year and also a reduction in total reported syphilis of approximately 50 per cent in 1957
